A central question on Kitaev materials is the effects of additional couplings on the Kitaev model, which is proposed to be a candidate for realizing topological quantum computations. However, two spatial dimensions typically suffer the difficulty of lacking controllable approaches. In this work, using a combination of powerful analytical and numerical methods available in one dimension, we perform a comprehensive study on the phase diagram of a one-dimensional version of the spin-1/2 Kitaev-Heisenberg-Gamma model in its full parameter space. A strikingly rich phase diagram is found with nine distinct phases, including four Luttinger liquid phases, a ferromagnetic phase, a Néel ordered phase, an ordered phase of distorted-spiral spin alignments, and two ordered phases, which both break a $D_3$ symmetry albeit in different ways, where $D_3$ is the dihedral group of order six. Our work paves the way for studying one-dimensional Kitaev materials and may provide hints to the physics in higher-dimensional situations.

DOI: 10.1103/PhysRevResearch.2.033268

I. INTRODUCTION

The Kitaev spin-1/2 model on the honeycomb lattice [1] with anisotropic bond-dependent Ising interactions is proposed to host exotic quasiparticle excitations, including Majorana fermions, and non-Abelian anyons under applied magnetic fields. A remarkable feature of these excitations is that their braiding and fusion operations can be used to realize topological quantum computations [2]. For this reason, the model has stimulated intense research interest in the past decade [2–4].

It was first proposed that the Mott insulating $A_2$IrO$_4$ (A=Li, Na) compounds on the honeycomb lattice provide a platform for realizing the Kitaev spin-1/2 model [5]. The $d^5$ configuration of the magnetic Ir$^{4+}$ ion is subject to strong cubic crystal fields due to the surrounding octahedral environment formed by O$^{2-}$ ions. The Ir$^{4+}$ ion is in its low-spin configuration with all five electrons residing in the three $t_{2g}$ orbitals, and the spin and effective orbital angular momenta are $S = 1/2$ and $L = 1$, respectively. Strong spin-orbit coupling plays a crucial role in transferring the oxygen-mediated orbital-dependent superexchange Hamiltonian to an anisotropic effective spin-1/2 model. Indeed, due to strong spin-orbit couplings, the ground state of a single ion is a Kramers doublet with a total angular momentum $j = 1/2$, and the projection of the superexchange model to the $j = 1/2$ subspace is the desired bond-dependent Kitaev spin-1/2 model [5].

However, the direct overlaps between Iridium $d$-orbitals introduce additional interactions, including the Heisenberg coupling [6] and the off-diagonal symmetric Gamma coupling [7]. The generalized Kitaev models including these additional terms were proposed [8–11], and have been supported by many theoretical and experimental studies to be good descriptions for real materials [12–25]. In real materials, the signs of the couplings [26] are determined to be ferromagnetic (FM) for the Kitaev coupling, antiferromagnetic (AFM) for the Heisenberg coupling, and AFM for the Gamma coupling. Besides iridium oxides, other 4$d$ transition metal materials including $\alpha$-RuCl$_3$ are also candidates for the Kitaev model although the spin-orbit coupling strength is significantly weaker [27,28]. Recently there has been experimental evidence for Majorana excitations in the $\alpha$-RuCl$_3$ material [29]. We also note that there have been proposals for realizing Kitaev materials in $f$-electron systems, which have an AFM Kitaev coupling [30].

Many theoretical efforts have been devoted to studying the phase diagram and fractional excitations of the Kitaev model on the honeycomb lattice augmented with Heisenberg and Gamma couplings [6,26,31–38]. However, most of the studies are based on a classical analysis, mean field theories, or exact diagonalization (ED) on a small system, and a controllable understanding is usually lacking, which is a typical difficulty in two dimension (2D). On the other hand, in one dimension (1D), there are more reliable analytical and large-scale numerical methods to study the low-energy properties, including bosonization [39,40], conformal field theory (CFT) [41–45], and the density matrix renormalization group (DMRG) methods [46–48]. Hence, a detailed investigation of a 1D version of the Kitaev model may shed light on the physics in 2D. It also provides a starting point for an extrapolation to 2D by coupling the 1D chains together and tuning the interchain coupling strength from weak to strong. In addition, a study of
FIG. 1. Sketch of the phase diagram for the spin-1/2 Kitaev-Heisenberg-Gamma chain with eleven phases in total, and cartoon plots for the long-range and quasi-long-ranger orders in the corresponding phases. The full parameter space is a two dimensional unit sphere parametrized by the polar and azimuthal angles \( \theta \) and \( \phi \). Due to the equivalence \((K, J, -\Gamma) \simeq (K, J, \Gamma)\), only the front half of the unit sphere corresponding to \( \theta, \phi \in [0, \pi] \) is shown. The \((\theta, \phi)\) coordinates of the \( K, -K, \Gamma, \) AFM1, FM1, AFM2, FM2, AFM3, FM3 points are \((\frac{\pi}{2}, 0), (\frac{\pi}{2}, \pi), (\frac{\pi}{2}, \frac{2\pi}{3}), (0, \#), (\pi, \#), (\frac{\pi}{2}, \frac{\pi}{3}), (\pi - \arctan(2), 0)\) and \((\arctan(2), \pi)\), respectively, in which the symbol ‘#’ is used when the value of \( \phi \) can be arbitrarily chosen. We note that the ‘Emergent SU(2)’ and ‘\( O_b \rightarrow D_3 \)’ phases on the equator are parts of the ‘LL1’ and ‘\( D_3\)-breaking II’ phases, respectively, hence they are written in green (rather than blue) color in Fig.1 and will be left for further study. The plot in Fig.1 is only schematic, and the precise phase boundaries are shown in Fig. 2 as determined by DMRG numerics. Also, only half of the parameter space within the range \( \theta, \phi \in [0, \pi] \) is shown due to the equivalence \((\theta, \phi) \simeq (\theta, 2\pi - \phi)\) [see Eq. (3)].

From an analytic point of view, there are six special points with explicit or hidden SU(2) symmetries, which provide starting points for a perturbative analysis in the regions nearby. More precisely, the AMF1 and FM1 points located at the north and south poles are explicitly SU(2) symmetric.
from the AFM points are not large. The low-energy field RG analysis, which is controllable as long as the deviations on systems of \(L\) are plotted as solid white lines, except the line segment separating the range not limited to the spin-1 \(s\) symmetric \( SU(2) \) critical theory. In this way, five phases can be understood, including the Luttinger liquid phases “LL1,” “LL2,” and “LL3” (“LL” is “Luttinger liquid” for short), and the “Néel” and “FM” phases, respectively. A brief description of the “LL2” phase is also included in Sec. IV. In Sec. V, the “LL4” phase is identified as the “LL4” phase. DMRG numerics provide evidence for the existence of the “LL4” phase as shown in Fig. 2.

When \( J \) approaches zero, the Luttinger parameter diverges, hence higher-order effects eventually become important and drive the system into a strong coupling limit. By a careful combination of strong coupling and symmetry analysis, two different types of symmetry breaking patterns are identified for small \( |J| \), namely, \( D_{3d} \rightarrow Z_2^{(i)} \) and \( D_{3d} \rightarrow Z_2^{(ii)} \), where \( Z_2^{(i)} \) and \( Z_2^{(ii)} \) are two different \( Z_2 \) groups. Since \( D_{3d}/Z_2 \cong D_3 \), both phases break the \( D_3 \) symmetry, which is the origin of the name “\( D_3\)-breaking” for the phases in Fig. 1. The type of \( D_3\)-breaking order is selected by the sign of the coupling constant, the determination of which requires a third-order perturbation calculation. We do not perform such a difficult high-order perturbation calculation, but instead turn to a classical analysis. Based on the classical analysis, we find that the “\( D_3\)-breaking” region can be divided into two subregions corresponding to the “\( D_3\)-breaking I” and the “\( D_3\)-breaking II” phases as shown in Fig. 1, which have \( Z_2^{(i)} \) and \( Z_2^{(ii)} \) as the unbroken symmetry groups, respectively. Our DMRG numerics provide evidence for the existence of these two \( D_3\)-breaking phases.

The rest of the paper is organized as follows, where each section is made self-contained for the convenience of the readers who are interested in specific phases in the phase diagram. In Sec. II, the model Hamiltonian is introduced, and the sublattice rotations are discussed which reveal the hidden SU(2) symmetric points AFM\(i\) and FM\(i\) \((i = 1, 2, 3)\) shown in Fig. 1. In Secs. III and IV, we combine RG calculations, symmetry analysis, and numerics together to study the “LL1” and the “Néel” phases, respectively. A brief description of the “LL2” phase is also included in Sec. IV. In Sec. V, the “d-Spiral” phase is studied. The symmetry breaking pattern is identified to be \( D_{3d} \rightarrow D_2 \), and the spin alignments are shown to exhibit a “distorted” spiral pattern. In Sec. VI, the
“LL3” phase is investigated, again by a combination of RG, symmetry, and numerical analysis. Section VII is devoted to a discussion of the “LL4” and D3-breaking I, II phases. In Sec. VIII, the “FM” phase is discussed. Finally in Sec. IX, we briefly summarize the main results and open questions of the paper.

II. MODEL HAMILTONIAN

A. The Hamiltonian

We consider a spin-1/2 Kitaev-Heisenberg-Gamma (KHI) chain [7] in zero magnetic field defined as

$$H = \sum_{\langle ij \rangle \in \gamma \text{ bond}} \left[ KS_x^i S_x^j + J \vec{S}_i \cdot \vec{S}_j + \Gamma (S_y^i S_x^j + S_y^j S_x^i) \right],$$  

(1)

in which \(i\) and \(j\) are two sites of nearest neighbors; \(\gamma = x, y\) is the spin direction associated with the \(\gamma\) bond shown in Fig. 3(a); \(\alpha \neq \beta\) are the two remaining spin directions other than \(\gamma\); \(K, J, \text{ and } \Gamma\), are the Kitaev, Heisenberg, and Gamma couplings, respectively. The terms in \(H\) are spelled out explicitly in Ref. [54]. Throughout this work, we parametrize \(K, J, \text{ and } \Gamma\) as

$$J = \cos(\theta),$$

$$K = \sin(\theta) \cos(\phi),$$

$$\Gamma = \sin(\theta) \sin(\phi),$$

(2)

in which \(\theta \in [0, \pi]\) and \(\phi \in [0, 2\pi]\).

It is straightforward to observe that a global spin rotation \(R(\vec{n}, \theta) : (S_x^i, S_y^i, S_z^i) \rightarrow (S_x^i, S_y^i, S_z^i)\) leaves \(K\) and \(J\) invariant but changes the sign of \(\Gamma\), in which \(R(\vec{n}, \theta)\) represents a rotation in spin space around the \(\vec{n}\) direction by an angle \(\theta\). Hence,

$$(K, J, -\Gamma) \simeq (K, J, \Gamma),$$

(3)

i.e., \((\theta, \phi) \simeq (\theta, 2\pi - \phi)\). Due to this equivalence, the phase diagram will be studied within the parameter range \(\theta \in (0, \pi)\), \(\phi \in (0, \pi)\). It is apparent that the north and south poles where \(K, \Gamma\) vanish have explicit SU(2) symmetries: \(\theta = 0\) corresponds to the AFM Heisenberg model, and \(\theta = \pi\) is the FM Heisenberg model. These two SU(2) symmetric points are denoted as AFM1 and FM1 in the phase diagram in Fig. 1.

B. Sublattice transformations and hidden SU(2) symmetries

In this section, we briefly review the six- and four-sublattice rotations [31,53,55,56], and show that they unveil several points in the parameter space which have hidden SU(2) symmetries. These hidden SU(2) symmetric points provide starting points for a perturbative study of the regions surrounding them.

1. The six-sublattice rotation

The six-sublattice rotation \(U_6\) is defined as [53,56]

sublattice 1 : \((x, y, z) \rightarrow (x', y', z')\),

sublattice 2 : \((x, y, z) \rightarrow (-x', -y', -z')\),

sublattice 3 : \((x, y, z) \rightarrow (y', z', x')\),

sublattice 4 : \((x, y, z) \rightarrow (-y', -x', -z')\),

sublattice 5 : \((x, y, z) \rightarrow (z', x', y')\),

sublattice 6 : \((x, y, z) \rightarrow (-z', -y', -x')\),

(4)

in which “sublattice \(i\)’ \((1 \leq i \leq 6)\) represents all the sites \(i + 6n (n \in \mathbb{Z})\) in the chain, and we have abbreviated \(S^\alpha (S^\alpha)\) as \(\alpha (\alpha')\) for short (\(\alpha = x, y, z\)). The Hamiltonian \(H' = U_6HU_{-6}^-\) in the six-sublattice rotated frame is

$$H' = \sum_{\langle ij \rangle \in \gamma \text{ bond}} \left[ -KS_x^i S_x^j - \Gamma (S_y^i S_x^j + S_y^j S_x^i) \right] - J(S_y^i S_x^j + S_y^j S_x^i + S_z^i S_z^j),$$

(5)

in which \(\gamma = x, y, z\) has a three-site periodicity shown in Fig. 3(b), and \(S_x^i\) is denoted as \(\vec{S}_i\) for simplicity. The terms in \(H'\) are spelled out explicitly in Ref. [54].

It is clear from Eq. (5) that while the Kitaev and Gamma terms acquire a form similar to the Heisenberg model (but with unequal couplings along different spin directions) in the six-sublattice rotated frame, the Heisenberg \(J\) term loses its form. Indeed, \(H'\) is SU(2) invariant when \(K = \Gamma, J = 0\). Combining \(U_6\) with Eq. (3), we see that \((\theta = \pi/2, \phi = \pi/4)\) and \((\theta = \pi/2, \phi = 3\pi/4)\) have hidden SU(2) symmetries with FM and AFM couplings, respectively, which are denoted as the FM2 and AFM2 points in the phase diagram shown in Fig. 1.

2. The four-sublattice rotation

The four-sublattice rotation \(U_4\) is defined as [31,55]

sublattice 1 : \((x, y, z) \rightarrow (-x', y', -z')\),

sublattice 2 : \((x, y, z) \rightarrow (-x', -y', z')\),

sublattice 3 : \((x, y, z) \rightarrow (x', -y', -z')\),

sublattice 4 : \((x, y, z) \rightarrow (x', y', z')\),

(6)

in which “sublattice \(i\)’ \((1 \leq i \leq 4)\) represents all the sites \(i + 4n (n \in \mathbb{Z})\) in the chain, and we have again dropped the spin symbol \(S\) for simplicity. The Hamiltonian \(H'' = U_4HU_{-4}^-\) in the four-sublattice rotated frame acquires the form

$$H'' = \sum_{\langle ij \rangle \in \gamma \text{ bond}} \left[ (K + 2J)S_x^i S_x^j - J\vec{S}_i \cdot \vec{S}_j \right] + \epsilon(\gamma)\Gamma (S_y^i S_x^j + S_y^j S_x^i),$$

(7)
in which the bonds $\gamma = x, y, \tilde{x}, \tilde{y}$ has a four-site periodicity as shown in Fig. 3(c); the function $\epsilon(\gamma)$ is defined as $\epsilon(x) = \epsilon(y) = -\epsilon(\tilde{x}) = -\epsilon(\tilde{y}) = 1$; $\tilde{S}_i^\gamma = S_i^\gamma$; and $\tilde{S}_i^\gamma$ is denoted as $\tilde{S}_i$ for short. The terms in $H''$ are spelled out explicitly in Ref. [54].

When $\Gamma = 0$, $U_4$ defines a duality transformation for the Kitaev-Heisenberg chain parametrized by the two coupling constants ($K, J$), and there is the equivalence [31]

\[(K, J, \Gamma = 0) \simeq (K + 2J, -J, \Gamma = 0). \quad (8)\]

If further $K + 2J = 0$, $H''$ describes an SU(2) symmetric Heisenberg model with a coupling constant equal to $-J$. The two hidden SU(2) symmetric points $[\theta = \pi - \arctan(2), \phi = 0]$ and $[\theta = \arctan(2), \phi = \pi]$ thus revealed are denoted as AFM3 and FM3 in Fig. 1, respectively.

It is straightforward to observe that the Kitaev points are self-dual under $U_4$. Setting $\Gamma = 0$ and normalizing the transformed parameters according to $K^2 + J^2 + \Gamma^2 = 1$ (where $K' = K + 2J$, $J' = -J$, $\Gamma' = 0$), $U_4$ establishes the equivalences:

\[\text{[AFM1, } K] \simeq [K, \text{ AFM3}], \]
\[\text{[AFM3, FM1]} \simeq [\text{AFM1, FM3}], \]
\[\text{[FM1, } -K] \simeq [\text{FM3, } -K], \quad (9)\]

in which $[A, B]$ represents the arc between the points $A$ and $B$ on the circular boundary of Fig. 1.

C. Summary of the phase diagram

In this section, we make a quick summary of the phase diagram shown in Fig. 1.

On the equator, the “$O_h \rightarrow D_4$” and “emergent SU(2)$_1$” phases occupy the $\phi$ intervals $[\phi_c', \phi_c]$ and $[\phi_c, \pi]$, respectively, in which $\phi_c' \simeq 0.10\pi$ and $\phi_c \simeq 0.33\pi$ as determined in Ref. [53]. When $J \neq 0$, the emergent SU(2)$_1$ and $O_h \rightarrow D_4$ phases extend to the LL1 and D3-breaking II phases, respectively. We note that the nature of the narrow hatched region close to the $K$ point highlighted with magenta color in Fig. 1 remains unclear, which will be left for further study.

For the four Luttinger liquid phases in Fig. 1, the Luttinger parameters have been calculated numerically based on the method described in Ref. [57]. The results are shown as color plots in Fig. 2, in which the blue color is used to signify the situation where no reliable Luttinger parameter can be extracted. As can be seen from Fig. 2, it is a very nice result that nearly all the phase boundaries in Fig. 1 can be determined from this Luttinger parameter calculation. We note that the phase boundaries in Fig. 1 are only schematic, and their precise shapes should be referred to Fig. 2.

The cartoon plots for the phases with $J \neq 0$ are collected in Fig. 1, all referring to the original frame without any sublattice rotation. The patterns of the spin orientations in the ordered phases Neel, d-Spiral, D3-breaking I, II, and FM are plotted, where the $z$ direction is chosen to be vertical for the D3-breaking I, II phases, and perpendicular to the plane for the other ordered phases. The quasi-long-range orders in the Luttinger liquid phases LL$i$ ($i = 1, 2, 3, 4$) are also shown, in which the $z$ axes are all fixed to be pointing upwards. The black arrows represent the site-dependent directions of the quantization axes for the longitudinal fluctuations, whereas the shaded blue ellipses represent the plane of the transverse fluctuations which dominate over the longitudinal fluctuations in all four Luttinger liquid phases. We note that since the low-energy Hamiltonian for the LL4 phase in the six-sublattice rotated frame has an FM-type quasi-long-range order, there is no oscillation accompanying the power decay in the cartoon plot of the LL4 phase in Fig. 1.

Finally, we make a comment about the ED and DMRG numerics that we have performed in this work. For systems with open boundary conditions, the DMRG method was used on chains with length up to $L = 144$ sites. For some of the calculations, such as the ground state energy computations determining the boundaries of the phases, we used ED on chains up to $L = 24$ sites long, while DMRG with periodic boundary conditions was used for chains of $L = 36$ sites. In all the cases, we have checked that our DMRG results are converged using up to $m = 1000$ states with a truncation error below $10^{-7}$.

III. THE LL1 PHASE

In this section, we show that the region denoted by LL1 in Fig. 1 is described by the gapless Luttinger liquid theory. The system exhibits a site-dependent quantization axis for the longitudinal fluctuations with the original frame as shown in Fig. 4. The strategy for analyzing the LL1 phase is to take the emergent SU(2)$_1$ phase of the Kitaev-Gamma chain [53] on the equator of Fig. 1 as the unperturbed Hamiltonian, and treat the Heisenberg term as a small perturbation using a perturbative RG analysis. To facilitate analysis, we work in the six-sublattice rotated frame defined by Eq. (4) throughout this section unless otherwise stated.

A. Brief review of the emergent SU(2)$_1$ phase

When $J = 0$ in Eq. (1), the system reduces to a Kitaev-Gamma chain and has been studied in Ref. [53]. In this section, we briefly review the emergent SU(2)$_1$ phase when $\phi_c \leq \phi \leq \pi$ and $\theta = \pi/2$, which provides an RG perturbative starting point for analyzing the LL1 and FM phases on the two different sides of the equator. Due to the equivalence $\Gamma' \simeq -\Gamma$, we will consider the equivalent region in the other half of the equator, i.e., $\theta = \pi/2, \phi \in (\pi, 2\pi - \phi_c)$. In particular, the

FIG. 4. Site-dependent quantization axes for the longitudinal fluctuations in the LL1 phase within the original frame. The black arrows denote the directions of the quantization axes, and the solid blue ellipses represent the transverse fluctuations. The red line represents the AFM quasi-long-range order for the longitudinal and transverse fluctuations defined in terms of the six-sublattice rotated frame. The $z$ direction in spin space is chosen to be pointing upwards, and the $y$ direction is along the chain pointing to the right.

033268-5
point $\phi = 5\pi/4$ has explicit SU(2) symmetry in the rotated frame.

The low-energy degrees of freedom in the emergent SU(2)$_1$ phase are $\hat{J}_L$, $\hat{J}_R$, and $g$, where $\hat{J}_L$ and $\hat{J}_R$ are the WZW left and right currents and $g$ is the SU(2)$_1$ primary field which is a $2 \times 2$ matrix [58–60]. At low energies, the lattice spin operators $\hat{S}_i$'s can be expressed in terms of $\hat{J}_L$, $\hat{J}_R$, and $g$ using the following modified non-Abelian bosonization formula [53]:

$$\frac{1}{a} S^\alpha_i = D^\alpha_{ij} (J^\alpha_L + J^\alpha_R) + C^\alpha_{ij} (-\frac{1}{a} \partial_j g^\sigma),$$

in which $[j]$ (1 $\leq [j] \leq 3$) is defined as $j \equiv [j]$ mod 3, $\sigma^\alpha$ ($\alpha = x, y, z$) are the three Pauli matrices, and the WZW primary field $g$ is taken as dimensionless. Symmetry constraints lead to the following relations among the coefficients [53]:

$$E^\alpha_i = E^\alpha_j = E^\beta_i = E^\beta_j = E^\gamma_i = E^\gamma_j (= E_1),$$

$$E^\alpha_j = E^\alpha_i = E^\beta_j = E^\beta_i,$$

in which $E = C, D$. The low-energy Hamiltonian of the Kitaev-Gamma chain is [53]

$$H = \frac{2\pi}{3} v \int dx (\hat{J}_L \cdot \hat{J}_L + \hat{J}_R \cdot \hat{J}_R) - g_c \int dx \hat{J}_L \cdot \hat{J}_R,$$

in which $v$ is the spin velocity, and $g_c > 0$ is the marginally irrelevant coupling. The values of both $v$ and $g_c$ depend on the microscopic details, which in principle can be obtained from DMRG numerical calculations on the Kitaev-Gamma chain. We note that the spin-spin correlation functions can be calculated using Eqs. (10) and (12).

### B. Low-energy Hamiltonian

In this section, we derive the low-energy perturbation Hamiltonian by directly projecting the Heisenberg Hamiltonian to the low-energy space. The low-energy field theory is found to be the same as that of an XXZ chain with a quantization axis along the (1,1,1) direction. In practice, the spin operators within

$$H^I = \sum_{[ij] \in \gamma \text{ bond}} - J (S^x_i S^x_j + S^y_i S^y_j + S^z_i S^z_j),$$

are replaced by $\hat{J}_L$, $\hat{J}_R$, and $g$ using the modified non-Abelian bosonization formula in Eq. (10). This method is essentially a first-order perturbation treatment of the Heisenberg term, and the coupling constants thus obtained are not accurate in the sense that they acquire renormalizations along the RG flow. On the other hand, by performing a careful symmetry analysis on the low-energy theory, we have justified the use of this first-order perturbation method in capturing the essential physics.

To obtain the perturbation Hamiltonian, the following operator product expansion (OPE) formula for the Néel order fields is needed:

$$N^\alpha(x + a) N^\mu(x) = 2 \delta^\alpha\mu - 4\pi a e^{i\phi/a} (J^\alpha_L - J^\mu_R)$$

$$+ (2\pi a)^2 [2J^\alpha L^\mu R + J^\mu L^\alpha R + J^\lambda L^\mu R]$$

$$+ \delta^\alpha\mu (2J^\alpha L \cdot \hat{J}_R + \frac{1}{2} \hat{J}_L \cdot \hat{J}_L + \frac{1}{2} \hat{J}_R \cdot \hat{J}_R)$$

$$+ \ldots ,$$

in which $x$ is a spatial coordinate, $a$ is the lattice constant, $\lambda$, $\mu = x, y,$ and $z$ are spin directions, $[\ldots]$ and $[\ldots]$ in the superscripts denote symmetrization and antisymmetrization of the indices, respectively, and only terms up to quadratic order in the WZW currents are kept. Equation (14) can be derived from the affine symmetry of the SU(2)$_1$ WZW model as discussed in detail in Ref. [54].

Plugging Eq. (10) into Eq. (13) and using Eq. (14), we obtain

$$H^I \rightarrow - \frac{1}{3} J a \int dx [u_{1} (J^0_R - J^0_L) + u_{2} J^1_L J^1_R + u_{3} \hat{J}_L \cdot \hat{J}_R$$

$$+ u_{4} (J^2_L J^0_R + J^0_R J^2_L) + u_{5} (\hat{J}_L \cdot \hat{J}_L + \hat{J}_R \cdot \hat{J}_R)],$$

in which only the relevant and marginal terms are kept; the arrow $\rightarrow$ indicates that it is not an exact equality but only a projection; $\hat{J}_L \cdot \hat{J}_R = \sum_{i=0,1,2} J^i_L J^i_R$, (s, $s' = L, R$), where

$$J^0_s = \frac{1}{\sqrt{3}} (J^x_s + J^y_s + J^z_s);$$

$$J^1_s = \frac{1}{\sqrt{6}} (2J^x_s - J^y_s - J^z_s);$$

$$J^2_s = \frac{1}{\sqrt{2}} (J^y_s - J^z_s);$$

and the coefficient $u_2$ is

$$u_2 = \frac{1}{2} [(D_x)^2 + (D_z)^2] + 12\pi^2 [(C_x)^2 + (C_z)^2].$$

The values of the other coefficients $u_i$'s ($i = 1, 3, 4,$ and 5) are not important for our purpose and can be found in Ref. [54], in which a detailed derivation of Eq. (15) is also included. Furthermore, we have performed a careful symmetry analysis in the low-energy Hamiltonian showing that Eq. (15) contains all the relevant and marginal terms allowed by symmetry within the SU(2)$_1$ WZW model (for details, see Ref. [54]). Therefore the low-energy Hamiltonian in Eq. (15) is enough and complete to capture the physics as long as $|J|$ is small.

In the SU(2)$_1$ WZW theory, $J^0_L J^0_R (\lambda = L, R)$ is equal to $\frac{1}{4} \hat{J}_L \cdot \hat{J}_R$ (see Ref. [54]), hence it does not give an independent contribution. In addition, the only nontrivial SU(2) breaking term $J^0_L - J^0_R$ can be eliminated by a chiral rotation [61–63]. As a result, the only nontrivial SU(2) breaking term in the low-energy theory of the KHG chain is $J^2_L J^2_R$. This shows that the low-energy physics is the same as that of an XXZ chain with a quantization axis along the (1,1,1) direction. Whether the system remains gapless or develops an order is determined by the sign of the coupling $-\frac{1}{4} J u_2$.

To gain a simple understanding as to why the (1,1,1) direction is special, here we give a brief description of the symmetry group in the six-sublattice rotated frame. With a nonzero Heisenberg term, the symmetry transformations of the Hamiltonian $H^I$ in Eq. (5) are

1. $T : (S^x_i, S^y_i, S^z_i) \rightarrow (-S^x_i, -S^y_i, -S^z_i),$

2. $R_{1} J : (S^x_i, S^y_i, S^z_i) \rightarrow (-S^{x}_{10, -10}, -S^{y}_{10, -10}, -S^{z}_{10, -10}),$

3. $R_{q} T_{a} : (S^x_i, S^y_i, S^z_i) \rightarrow (S^x_{i+1}, S^y_{i+1}, S^z_{i+1}),$
in which $T$ is time reversal; $T_0$ is translation by one lattice site; $I$ is the spatial inversion around the point $C$ in Fig. 3(b); and $R_x = R(\hat{n}_x, -2\pi/3)$, $R_I = R(\hat{n}_I, \pi)$, where

$$\hat{n}_x = \frac{1}{\sqrt{3}}(1, 1, 1)^T, \hat{n}_I = \frac{1}{\sqrt{2}}(1, 0, -1)^T.$$ (19)

In Eq. (18), the choice of the inversion center in the definition of $I$ is well defined modulo three. If another inversion center $5 + 3n$ is chosen, then $S_{10-i}^\alpha (\alpha = x, y, z)$ in the second line in Eq. (18) should be correspondingly replaced by $S_{10+n-i}^\alpha$. According to Eq. (18), the symmetry group $G_1$ of $H'$ is

$$G_1 = \langle T, R_x T_a, R_I I \rangle.$$ (20)

In the continuum limit, the lattice is coarse-grained and the effect of $T_0$ is smeared. Hence, it is not a surprise that the symmetry operation $R_x T_a$ picks out $\hat{n}_a$ [i.e., the $(1,1,1)$ direction] to be the quantization axis in the low-energy theory (which is also justified by the symmetry analysis on the low-energy Hamiltonian as discussed in Ref. [54]).

Finally, we make a comment on the group structure of $G_1$ which will be used in Sec. VII. Since $T_{3a} = (R_x T_a)^5$ belongs to $G_1$, it is legitimate to consider the quotient group $G_1/(T_{3a})$. In our case, time reversal plays the role of “inversion” in the spin space, since $T$ changes the signs of the spin operators. Neglecting the spatial components in $R_x T_a$ and $R_I I$, the spin operations $R_x$ and $R_I$ generate the symmetry group of a regular triangle as shown in Fig. 5. Since $D_{3d} = D_3 \times Z_2$ in which $D_3$ is the symmetry group of a regular triangle and $Z_2$ is generated by the inversion operation [65], we see that $\langle T, R_x, R_I \rangle \cong D_{3d}$. As proved in Ref. [54], $\langle T, R_x T_a, R_I I \rangle/(T_{3a})$ is isomorphic to $D_{3d}$ even when the spatial components in the operations are included. As a result, $G_1/(T_{3a}) \cong D_{3d}$. This shows that the group structure of $G_1$ is

$$G_1 \cong D_{3d} \times 3Z,$$

in which $3Z = \langle T_{3a} \rangle$.

C. Phase diagram

In a perturbative treatment of the Heisenberg term, we will assume that $|J| \ll va, g, a$. With a nonzero Heisenberg term, the low-energy Hamiltonian is modified to

$$H = \frac{2\pi}{3}v' \int dx (\vec{J}_L \cdot \vec{J}_L + \vec{J}_R \cdot \vec{J}_R)$$
$$-2\pi v' \int dx \left[ y_L (J_L^x J_R^x + J_L^y J_R^y) + y_I J_L^z J_R^z \right],$$ (22)

in which according to Eq. (15),

$$y_L = \frac{1}{2\pi v'} \left[ g_x + \frac{1}{3} J_{au} \right],$$

$$y_I = \frac{1}{2\pi v'} \left[ g_x + \frac{1}{3} J_{au} (u_1 + u_2) \right].$$ (23)

In particular, since $u_2$ is always positive [as can be seen from Eq. (17)], we have $y_I > y_L$ when $J > 0$, and $y_I < y_L$ when $J < 0$. We note that in Eq. (22), the chiral term $J_L^y - J_R^y$ term is dropped according to the discussions in Sec. III B. The RG flow equations of $y_L$ and $y_I$ are of the Kosterlitz-Thouless (KT) type [64]:

$$\frac{dy_L}{dt} = -y_L y_I,$$

$$\frac{dy_I}{dt} = -y_L^2,$$

which are obtained by integrating out the modes with wavelengths between $a$ and $a + dI$. It is well known that the system flows to a strong coupling limit when $y_I < y_L$ and remains gapless when $y_I > y_L$ [64].

The phase diagram by tuning $J$ is shown in Fig. 6. Notice that this phase diagram can be easily understood from intuitive physical arguments. The $J > 0$ case introduces an FM-like term into the Hamiltonian since the coupling is $-J$ in the rotated frame. Thus the AFM fluctuations in the longitudinal direction are suppressed and the system has an easy-plane anisotropy, corresponding to the “LL” phase in Fig. 6, where LL is “Luttinger liquid” for short. Similarly, the $J < 0$ case has an easy-axis anisotropy which corresponds to the “Ordered” phase in Fig. 6. We note that Fig. 6 is for a fixed background Kitaev-Gamma chain, i.e., the value of $\phi$ in Fig. 1 is fixed. By varying $\phi$, the gapless phase in Fig. 6 extends to the LL1 phase in Fig. 1, whereas the “Ordered” phase in Fig. 6 is below the equator, which will be shortly shown to be the FM phase in Fig. 1. We also note that the 0-direction (i.e., the longitudinal direction) in Eq. (22) is the (111) direction, which becomes staggered in the original frame according to Eq. (4). A sketch of the site-dependent quantization axis is shown in

FIG. 5. $R_a$ and $R_I$ as symmetry transformations of a regular triangle in the spin space. The vertices of the regular triangle are represented by the three solid green circles. The axes are labeled as $S_\alpha (\alpha = x, y, z)$ to emphasize that we are considering the spin space.

FIG. 6. Phase diagram of the KHG chain by tuning $J$, where $\phi \in (\pi + \phi_0, 2\pi)$, in which LL is “Luttinger liquid” for short.
Fig. 4. However, the quantization axes in Fig. 4 are not precise since they can be distorted due to the renormalization effects of the spin operators along the RG flow similar to the origins of the $C_1$, $C_2$ coefficients discussed in Eq. (10).

When $J$ is negative, we have shown that the system develops a Néel long-range order along the (111) direction. However, the alignments of the spins are distorted due to the difference in $C_1$ and $C_2$. Using Eq. (10) and assuming a nonzero expectation value for $N^0 = \frac{1}{\sqrt{3}}(N^x + N^y + N^z)$, the spin polarizations have a six-site periodicity,

$$\langle \vec{S}_{1+6n} \rangle = \frac{1}{\sqrt{3}} N(C_1, C_1, C_2)^T,$$

$$\langle \vec{S}_{2+6n} \rangle = \frac{1}{\sqrt{3}} N(-C_1, -C_2, -C_1)^T,$$

$$\langle \vec{S}_{3+6n} \rangle = \frac{1}{\sqrt{4}} N(C_2, C_1, C_1)^T,$$

$$\langle \vec{S}_{4+6n} \rangle = \frac{1}{\sqrt{4}} N(-C_1, -C_1, -C_2)^T,$$

$$\langle \vec{S}_{5+6n} \rangle = \frac{1}{\sqrt{3}} N(C_1, C_2, C_1)^T,$$

$$\langle \vec{S}_{6+6n} \rangle = \frac{1}{\sqrt{3}} N(-C_2, -C_1, -C_1)^T,$$ (25)

in which $n \in Z$ and $N = \langle N^0 \rangle$.

Recall that the results in Eq. (25) are within the six-sublattice rotated frame. To obtain the spin orientations in the original frame, it is enough to perform the inverse of the transformation defined in Eq. (4). It is straightforward to verify that

$$\langle \vec{S}^{(0)}_1 \rangle = \frac{1}{\sqrt{3}} N(C_1, C_1, C_2)^T,$$ (26)

where the superscript “(0)” is used to denote the spin operators in the original frame. Clearly, Eq. (26) represents an FM order along the $(C_1, C_1, C_2)$ direction. This provides an understanding of the FM phase in Fig. 1 in the region close to the equator.

D. Numerical results

To determine the range of the LL1 phase, we study the ground state energy $E$ as a function of $\theta, \phi$. ED calculations are performed for periodic systems of $L = 24$ sites in (a), $L = 12, 24$ sites in (b). In (b), DMRG simulations with periodic boundary conditions were performed on $L = 36$ sites chain.
\[
\begin{align*}
  f(j) &= u(j) + (-)^j s(j). 
  \\
  u(j) &= \frac{1}{2} f(j - 1) + \frac{1}{2} f(j) + \frac{1}{2} f(j + 1), 
  \\
  s(j) &= (-)^j \left[ -\frac{1}{2} f(j - 1) + \frac{1}{2} f(j) - \frac{1}{2} f(j + 1) \right].
\end{align*}
\]

Hence \( E_A \) can be obtained from the numerical result of \( h(x) \) by applying Eq. (31).

We have used this method to study the Luttinger parameters in the whole LL1 phase, and the results are displayed in Fig. 2 where the magnitudes of \( K \) are represented by different colors. This provides direct numerical evidence for the entire region enclosed by the phase boundary determined in Fig. 7 to be a Luttinger liquid phase. On the other hand, as can be seen from Fig. 2, the Luttinger liquids percolate into the FM phase. However, we note that this is a finite size artifact. As discussed in Sec. III C, the phase transition between the LL1 and FM phases is second-order. Since a gap \( E_g \sim e^{-c_1/\sqrt{|\Gamma|}} \) opens exponentially slowly in the FM phase close to the transition line \([44]\), the crossover system size \( L_c \) (only above which an order can be observed) grows exponentially at small \( J \), i.e., \( L_c \sim e^{c_2/\sqrt{|\Gamma|}} \). Thus the Luttinger liquid behavior can still be observed in an extended region in the FM phase in a finite size system.

IV. THE NÉEL PHASE

In this section, we study the Néel phase shown in Fig. 1. The spin alignments within the original frame are plotted in Fig. 8. The strategy that we take to analyze the Néel phase is to perform a perturbative RG analysis in the neighborhood of the AFM1 point located at the north pole in Fig. 1. Numerics provide evidence for the Néel ordering to hold in the entire region marked as Néel in Fig. 1. Throughout the section, we work in the original frame, and the discussions will be based on the Hamiltonian given in Eq. (1).

A. RG analysis

We can perform a first-order perturbation treatment of the Kitaev and Gamma terms, by projecting \( H_K \) and \( H_I \) to the low-energy degrees of freedom using the non-Abelian bosonization formula \([44]\),

\[
\frac{1}{d} S^\alpha_i = J^\alpha_L + J^\alpha_R + (-)^{i+1} \frac{c}{2\pi d} \text{itr}(g \sigma^\alpha).
\]

in which \( D_1 = D_2 = 1, C_1 = C_2 = \frac{1}{\sqrt{2}} \), where \( c \) is a constant. Comparing with Eq. (10), the SU(2) symmetry is not broken in Eq. (32). Explicit calculations show that (for details, see Ref. [54]),

\[
H^K \to K a \int dx \left[ -\frac{2c^2}{2\pi^2 d^2} + \frac{3 + 2c^2}{2d} (\vec{J}_L \cdot \vec{J}_L + \vec{J}_R \cdot \vec{J}_R) \right. \\
\left. -\frac{1}{2} (J^1_L J^1_R + J^2_L J^2_R) + \vec{J}_L \cdot \vec{J}_R - (1 + 2c^2) J^1_L J^1_R \right] (33)
\]

and

\[
H^\Gamma \to 2c^2 \Gamma a \int dx \left[ (J^1_L J^1_R + J^2_L J^2_R) \right. \\
\left. + J^0_L (J^0_R + J^0_R) \right]. (34)
\]

We have performed a careful symmetry analysis of the low-energy field theories for both the \( \Gamma = 0 \) and \( \Gamma \neq 0 \) cases as discussed in details in Ref. [54], where it is shown that the first-order perturbation Hamiltonian is already enough and complete to capture the low-energy physics. Notice that the low-energy Hamiltonian is of an XXZ type in the absence of \( \Gamma \). Since the coefficient of the \( J^1_L J^1_R \) term is \( -K a (1 + 2c^2) \), when \( \Gamma = 0 \), the system has easy-plane and easy-axis anisotropies for \( K > 0 \) and \( K < 0 \), respectively.

The Luttinger liquid phase when \( K > 0 \) (and \( \Gamma = 0 \)) revealed by this analysis is the "LL2" phase shown in Fig. 1. The "LL2" phase has already been discussed in Ref. [50], and our DMRG numerics have confirmed the existence of the "LL2" phase as shown in Fig. 2. We note that the percolation of the Luttinger liquid behavior in the "LL2" phase to nonzero \( \phi \)'s is a finite size artifact. The quantization axis for the longitudinal fluctuation in the "LL2" phase is along the \( z \) axis as shown in Fig. 9. However, similar to the case of the LL1 phase, the quantization axes in Fig. 9 are not precise since they can be distorted due to the renormalization effects of the spin operators along the RG flow.

Next we perform an RG analysis of the low-energy Hamiltonian in Eq. (34) for nonzero \( \Gamma \). We will see that it belongs to the XYZ class as long as \( \Gamma \neq 0 \), and an Néel order develops. The low-energy perturbation Hamiltonian can be
written as
\[
\begin{pmatrix}
J^x_L & J^y_L & J^z_L \\
0 & 0 & 2c^2\Gamma a \\
0 & 0 & 2c^2\Gamma a
\end{pmatrix}
\begin{pmatrix}
J^x_R \\
J^y_R \\
J^z_R
\end{pmatrix} = \begin{pmatrix}
J^x_L \\
J^y_L \\
J^z_L
\end{pmatrix}.
\tag{35}
\]
The matrix kernel in Eq. (35) can be straightforwardly diagonalized. The eigenvalues are
\[
E_1 = 0,
E_\pm = c^2\Gamma a(k \pm \sqrt{8 + k^2}),
\tag{36}
\]
with the corresponding unnormalized eigenvectors
\[
\Psi_0 = (-1, 1, 0)^T, \\
\Psi_\pm = \left(\frac{1}{2}(k \mp \sqrt{8 + k^2}), \frac{1}{2}(k \mp \sqrt{8 + k^2}), 1\right)^T,
\tag{37}
\]
in which \(k = \frac{2 \pm \sqrt{4 + \frac{8}{c^2}}}{\Gamma a}\). Notice that as long as \(\Gamma > 0\), we always have \(E_+ > 0\) and \(E_- < 0\) regardless of the value of \(K\).

Next, let’s perform a rotation of the coordinate system, such that
\[
x' = \Psi_{-1} / |\Psi_{-1}|, \quad y' = \Psi_{+1} / |\Psi_{+1}|, \quad z' = \Psi_0 / |\Psi_0|.
\tag{38}
\]
Then in terms of the new coordinates, the marginal terms become
\[
-2\pi v \int dx (\lambda_x J^x_L J^x_R + \lambda_y J^y_L J^y_R + \lambda_z J^z_L J^z_R),
\tag{39}
\]
in which \(\lambda_x = (g_c + E_+)/(2\pi v), \lambda_y = (g_c + E_0)/(2\pi v), \) and \(\lambda_z = g_c/(2\pi v)\). In particular, when \(K = 0\), we have
\[
\lambda_x^{(0)} = \frac{1}{2\pi v} (g_c + \sqrt{2\pi^2 \Gamma a}), \\
\lambda_y^{(0)} = \frac{1}{2\pi v} (g_c - \sqrt{2\pi^2 \Gamma a}), \\
\lambda_z^{(0)} = \frac{1}{2\pi v} g_c,
\tag{40}
\]
in which \(\Gamma\) is assumed to be small, and only terms up to \(O(\Gamma)\) are kept. The superscript “(0)” in Eq. (40) is used to indicate that these are the initial values of the couplings before the RG flow. In what follows, we consider the case \(\Gamma > 0\), \(K = 0\) for simplicity. The case of a nonzero \(K\) can be discussed similarly.

The RG flow equations of \(\lambda_x, \lambda_y,\) and \(\lambda_z\) are [44] \(d\lambda_x / dl = -\lambda_x, \lambda_y, \lambda_z\), \(d\lambda_y / dl = -\lambda_x, \lambda_y, \lambda_z\), \(d\lambda_z / dl = -\lambda_x, \lambda_y, \lambda_z\), \(\tag{41}\)
which can be obtained from the OPE formula for the WZW current operators [44]. There are three constants of motion for Eq. (41) which take the following forms when \(K = 0\):
\[
\lambda_x^2(l) - \lambda_y^2(l) = \frac{c^2g_c\Gamma a}{4\pi^2 v^2}, \\
\lambda_x^2(l) - \lambda_z^2(l) = \frac{c^2g_c\Gamma a}{2\sqrt{2}\pi^2 v^2}, \\
\lambda_z^2(l) - \lambda_y^2(l) = \frac{-c^2g_c\Gamma a}{2\sqrt{2}\pi^2 v^2},
\tag{42}
\]
Solving Eq. (41) with initial conditions given in Eq. (40) (see Ref. [54] for derivation), we obtain
\[
\lambda_x, \lambda_y \sim \Lambda, \lambda_z \sim -\Lambda,
\tag{43}
\]
where \(\Lambda \to \infty\) as \(l \to \infty\). It is clear that the system flows to strong couplings at low energies.

To identify the phase corresponding to the strong coupling limit, we perform a chiral rotation \(R_L(\bar{\gamma}, \pi)\), which maps \(J^x_L, J^y_L, J^z_L\) to \((-J^x_L, J^y_L, -J^z_L)\), but leaves \(J^x_R\) unchanged. Then it is clear that the three couplings after the chiral rotation become \(\tilde{\lambda}_x, \tilde{\lambda}_y, \tilde{\lambda}_z \sim -\lambda_x \to -\infty\). On the other hand, as shown in Ref. [44], this strong coupling limit corresponds to a dimer order, i.e.,
\[
\text{tr} \tilde{g} \neq 0,
\tag{44}
\]
where \(\tilde{g} = U_L g\) is the SU(2) WZW field after the chiral rotation, in which \(U_L = e^{i\pi\alpha y\gamma} = i\alpha y\) is the chiral rotation matrix. Therefore Eq. (44) implies that
\[
itr (\alpha y \gamma) \neq 0,
\tag{45}
\]
i.e., there is a Néel order along the \(y'\) direction. In terms of the original coordinates, the Néel ordering is along \(y = \left(\frac{1}{2}, \frac{1}{2}, \frac{\pi}{2}\right)\), as can be seen from Eq. (38).

### B. Symmetry breaking

We make a discussion on the symmetry breaking pattern in the Néel phase. The symmetry transformations in the original frame for a general Kitaev-Heisenberg-Gamma chain are

1. \(T : \) \(\{S_i^x, S_i^y, S_i^z\} \to \{-S_i^x, -S_i^y, -S_i^z\}\),
2. \(T_{2a} : \) \(\{S_i^x, S_i^y, S_i^z\} \to \{S_{i+2}^x, S_{i+2}^y, S_{i+2}^z\}\),
3. \(T_{3}I : \) \(\{S_i^x, S_i^y, S_i^z\} \to \{S_{i+3}^x, S_{i+3}^y, S_{i+3}^z\}\),
4. \(R(\hat{n}_N, \pi) T_a : \) \(\{S_i^x, S_i^y, S_i^z\} \to \{-S_{i+1}^x, -S_{i+1}^y, -S_{i+1}^z\}\),
\(\tag{46}\)
in which \(\hat{n}_N = \frac{1}{\sqrt{2}}(1, -1, 0)^T\). Since \(T_{2a} = [R(\hat{n}_N, \pi) T_a]^2\), we conclude that the symmetry group \(G_N\) is
\[
G_N = \{T, T_{3}I, R(\hat{n}_N, \pi) T_a\}.
\tag{47}\]
The only broken symmetry in the Néel phase is the time reversal symmetry. The unbroken symmetry group \(H_N\) can be determined as
\[
H_N = \{R(\hat{n}_N, \pi) T_a, TT_{3}I\}.
\tag{48}\]
It is straightforward to verify that the most general pattern of the spin orderings which is invariant under \(H_N\) is given by
\[
S_j = (-)^j(a, a, b)^T.
\tag{49}\]
The values of the parameters \(a\) and \(b\) in Eq. (49) cannot be determined from pure symmetry analysis, and in general depend on \(K\). A plot of the spin alignments in Eq. (49) is shown in Fig. 8.

### C. Numerical results

Numerics provide evidence for the Néel phase to occupy the entire region above the equator in Fig. 1 excluding the LL1 and the d-Spiral phases. Figure 10 shows \(s_{\text{sd}}(r)\) (\(\alpha = x, y, z\))
versus $\sin(\pi r/L)$ extracted from the three-point formula in Eq. (31) at a representative point $(\theta = 0.36\pi, \phi = 0.25\pi)$ in the Néel phase, where $(-\gamma')s_{a0}(r)$ is the staggered component of the spin-spin correlation function $\langle S_i^z S_{i+r}^z \rangle$. The DMRG numerical results for three different system sizes $L = 48$, $96$, and $144$ are displayed with black, red and green curves, respectively. As can be seen clearly from Fig. 10, all the three $s_{a0}(r)$ ($\alpha = x, y, z$) approach constant values when $r \gg 1$, indicating a Néel long-range order. In addition, the patterns of the spin orderings are fully consistent with Eq. (49), where $a^2, b^2$ can be determined from the asymptotic values of $s_{a0}(r)$ at large $r$.

V. THE d-SPIRAL PHASE

In this section, we study the d-Spiral phase in Fig. 1. The spin orientations within the original frame are shown in Fig. 11. The symmetry breaking pattern in the d-Spiral phase is inferred from the symmetry breaking in the spiral phase [50] of the Kitaev-Heisenberg chain based on the assumption that there is no phase transition between the d-Spiral and the spiral phases. The spin orientations in the d-Spiral phase are predicted to exhibit a “distorted-spiral” pattern, which is supported by our DMRG numerics. Throughout this section, we work in the four-sublattice rotated frame defined in Eq. (6) unless otherwise stated.

A. Symmetry breaking for $\Gamma = 0$

1. Symmetry group for $\Gamma = 0$

When $\Gamma = 0$, the system reduces to a Kitaev-Heisenberg chain even in the four-sublattice rotated frame by virtue of the duality property as mentioned in Eq. (8). Hence, in this case, there is no difference between the original and four-lattice rotated frames if the symmetry group structure is concerned.

The symmetry transformations of the Kitaev-Heisenberg chain are

$$
\begin{align*}
&1. \quad T : \quad \langle S_i^x, S_i^y, S_i^z \rangle \to \langle -S_i^x, -S_i^y, S_i^z \rangle, \\
&2. \quad T_{2a} : \quad \langle S_i^x, S_i^y, S_i^z \rangle \to \langle S_{i+2}^x, S_{i+2}^y, S_{i+2}^z \rangle, \\
&3. \quad T_a I : \quad \langle S_i^x, S_i^y, S_i^z \rangle \to \langle S_{i+1}^x, S_{i+1}^y, S_{i+1}^z \rangle, \\
&4. \quad R(\hat{y}, \pi) : \quad \langle S_i^x, S_i^y, S_i^z \rangle \to \langle -S_i^x, S_i^y, S_i^z \rangle, \\
&5. \quad R(\hat{z}, -\pi/2) T_a : \quad \langle S_i^x, S_i^y, S_i^z \rangle \to \langle -S_i^x, S_i^y, S_i^z \rangle.
\end{align*}
$$

in which the inversion center for $I$ is taken to be the site 0. We note that all the other symmetry transformations can be generated by the operations in Eq. (50) as discussed in Ref. [54]. Thus the symmetry group of the Kitaev-Heisenberg chain is

$$
G_0 = \left\{ T, T_{2a}, T_a I, R(\hat{y}, \pi), R(\hat{z}, -\pi/2) T_a \right\}.
$$

Next we briefly describe the group structure of $G_0$ (for a detailed proof, see Ref. [54]). Since $T_{2a} = [R(\hat{z}, -\pi/2) T_a]^4$ belongs to $G_0$, it is legitimate to consider the quotient group $G_0/(T_{2a})$, whose group structure is (see Ref. [54])

$$
G_0/(T_{2a}) = [(Z_2 \times Z_2) \ltimes D_{ad}],
$$

in which from left to right, $Z_2 = \langle T_a I \rangle$, $Z_2 = \langle T_{2a} \rangle \mod T_{2a}$, and

$$
D_{ad} = \left\{ T, R(\hat{z}, -\pi/2) T_a, R(\hat{y}, \pi) T_a I \right\} / \langle T_{2a} \rangle.
$$

This shows that

$$
G_0 = [(Z_2 \times Z_2) \ltimes D_{ad}] \ltimes 4Z,
$$

in which $4Z = \langle T_{2a} \rangle$.

We make some comments on the geometrical meaning for the origin of $D_{ad}$. Notice that $D_{ad} = D_4 \times Z_2$, in which $D_4$ is the symmetry group of a square containing four reflections and four rotations, and $Z_2 = \langle i \rangle$, where $i$ is the inversion.
operation. In our case, time reversal acts as “inversion” in spin space, since it flips the signs of the spin operators. Neglecting the spatial components in \( R(\hat{z}, -\frac{\pi}{2}) T_a \) and \( R(\hat{y}, \pi) T_a I \), the spin operations \( R(\hat{z}, -\frac{\pi}{2}) \) and \( R(\hat{y}, \pi) \) generate the symmetry group of a square as shown in Fig. 12. As proved in Ref. [54], \( (T, R(\hat{z}, -\frac{\pi}{2}) T_a, R(\hat{y}, \pi) T_a I) / (T_{a\theta}) \) is isomorphic to \( D_{4d} \) even when the spatial components in the operations are included.

2. Symmetry breaking pattern for \( \Gamma = 0 \)

In this section, we discuss the spin ordering and the symmetry breaking pattern for the \( \Gamma = 0 \) case, i.e., the Kitaev-Heisenberg chain, and later extend the analysis to \( \Gamma \neq 0 \) in Sec. V B 2. The spin ordering for \( \theta \in [-K, FM3] \) located on the circular boundary in Fig. 1 has been worked out in Ref. [50] which exhibits a spiral pattern with a four-site periodicity. On the other hand, this region of parameter can be mapped to the FM-xy phase in Fig. 1 by the four-sublattice rotation. Therefore the system is FM aligned along \( \pm(110) \) direction in the four-sublattice rotated frame. In what follows, we determine the symmetry breaking pattern corresponding to this FM spin order within the four-sublattice rotated frame.

Let’s consider the little group of the FM-xy order, in which the spin alignments are \( \bar{S}_i \equiv (f, f, 0)^T \). Apparently, the spin alignments are invariant under both \( T_a I \) and \( T_{a\theta} \). Furthermore, although \( R(\hat{z}, -\frac{\pi}{2}) T_a \) and \( R(\hat{y}, \pi) T_a I \) do not leave the FM-xy order invariant, the spin orientations are invariant under the combinations

\[
c = \left( R\left(\frac{\hat{z}}{2}, -\frac{\pi}{2}\right) T_a \right)^2 \cdot T,
\]

\[
d = R\left(\frac{\hat{z}}{2}, -\frac{\pi}{2}\right) T_a \cdot R(\hat{y}, \pi) T_a I.
\]

It is easy to verify that \( c \) and \( d \) satisfy \( c^2 = d^2 = (cd)^2 = e \) modulo \( T_{a\theta} \). Comparing with the generator-relation representation for the group \( D_n \) [65]

\[
D_n = \langle \alpha, \beta | \alpha^n = \beta^2 = (\alpha\beta)^2 = e \rangle,
\]

we see that relations in Eq. (56) are satisfied for \( c \) and \( d \) with \( n = 2 \), hence the group generated by \( c \) and \( d \) (modulo \( T_{a\theta} \)) is isomorphic to \( D_2 \). Therefore the little group of the FM-xy order is

\[
\left( \mathbb{Z}_2 \times \mathbb{Z}_2 \right) \rtimes D_{4d} \rightarrow \left( \mathbb{Z}_2 \times \mathbb{Z}_2 \right) \rtimes D_2,
\]

in which \( T_{a\theta} \) has been dropped for simplicity. In particular, since \( |D_{4d}| / |D_2| = 4 \), the ground states are fourfold degenerate in which the spins align ferromagnetically along \( \pm(1, \pm 1, 0) \) directions. On the other hand, by transforming back to the original frame, it can be seen that the spin orientations show a spiral pattern as plotted in Fig. 11(a).

B. Symmetry breaking for \( \Gamma \neq 0 \)

1. Symmetry group for \( \Gamma \neq 0 \)

When \( \Gamma \) is nonzero, the symmetry operations of \( H'' \) in the four-sublattice rotated frame in Eq. (7) can be verified to be the following:

1. \( T : (S_x^i, S_y^i, S_z^i) \rightarrow (S_x^i, -S_y^i, -S_z^i) \).
2. \( R(\hat{y}, \pi) T_a I : (S_x^i, S_y^i, S_z^i) \rightarrow (S_{x-1}^i, S_{y+1}^i, -S_z^i) \).
3. \( R(\hat{z}, -\frac{\pi}{2}) T_a : (S_x^i, S_y^i, S_z^i) \rightarrow (S_{x+1}^i, S_{y-1}^i, S_z^i) \).\]

Where the inversion center is taken to be site 2 in Fig. 3(c). Therefore the symmetry group is

\[
G_3 = \left( T, R(\hat{y}, \pi) T_a I, R\left(\frac{\hat{z}}{2}, \frac{\pi}{2}\right) T_a \right).
\]

As discussed in Sec. V A 1, the group structure of \( G_3 \) is

\[
G_3 \cong D_{4d} \rtimes \mathbb{Z}_2
\]

in which \( D_{4d} \) is given by Eq. (53), and \( 4\mathbb{Z} = (T_{a\theta}) \). Comparing Eq. (61) with Eq. (54), \( G_3 \) is explicitly a subgroup of \( G_0 \), and there are two more generators in \( G_0 \) than in \( G_3 \), i.e., \( T_a I \) and \( T_{a\theta} \).

2. Symmetry breaking pattern for \( \Gamma \neq 0 \)

In this section, we discuss the symmetry breaking and the spin ordering for the \( \Gamma \neq 0 \) case. Let’s assume that \( T_{a\theta} \) is not broken, and we’ll consider the quotient group \( G_3 / G_2 \) in what follows. If there is no phase transition when \( \Gamma \) is tuned from nonzero to zero, then the symmetry breaking for a nonzero \( \Gamma \) has to be

\[
D_{4d} \rightarrow D_2,
\]

as a natural extension of the pattern in Eq. (58) for the \( \Gamma = 0 \) case.

Assuming the symmetry breaking to be \( D_{4d} \rightarrow D_2 \), next we solve the most general spin ordering which is invariant under \( D_2 \). Requiring the invariance of the spin ordering under the two generators \( \left( R(\hat{z}, -\frac{\pi}{2}) T_a \right)^2 \cdot T \) and \( R(\hat{z}, -\frac{\pi}{2}) T_a \).
ground states can be obtained by applying the operations in case in Fig. 11(a). We note that the other three degenerate spin orientations in Eq. (64) reduce back to the pattern of the spin orientations are fully consistent with Eq. (63). The value of θ is the gap $\Delta_1$ and $\Delta_2$ scales linearly with $L$, indicating a first-order phase transition. On the other hand, we find no divergence in $\partial^2 E(\theta, \phi)/\partial \theta^2$ when the lower boundary of the d-Spiral phase is traversed. Recall that there is a divergence in $\partial^2 E(\theta, \phi)/\partial \phi^2$ as a function of $\phi$ as discussed in Fig. 7(c), which determines the lower boundary between the d-Spiral phase and the LL1 phase shown by the solid black squares in Fig. 13(c) within the region $\phi \in [0.96\pi, \pi]$. Next we discuss the numerical evidence for the spin ordering in Eq. (63) within the four-sublattice rotated frame. Before going to that, we mention a subtlety in numerical calculations. The four symmetry breaking ground states only become exactly degenerate in the thermodynamic limit. The ground state of a finite size system can be some arbitrary linear combination of the four states, and the coefficients depend on the system size and numerical details. Because of this, random cancellations occur if the expectation values of the spin operators $\langle \vec{S}_i \rangle$ are directly computed. To circumvent this problem, we measure $\langle \vec{S}_i \rangle$ in the presence of a small field along the (110) direction, which is able to polarize the system to reside in one of the four nearly degenerate states so that the spins orient according to the pattern in Eq. (63). The value of this field should satisfy $\Delta E \ll |\mathbf{h}|L \ll E_c$, where $\Delta E$ is the finite size energy splitting among the four states, $E_c$ is the gap between the ground state multiplet and the excitations, and $|\mathbf{h}|$ is the magnitude of the applied field. Such choice of field leads to a degenerate perturbation within the ground state quartet, but no mixing is induced between the ground state subspace and the excitations.

Figure 14 shows the measured values of $S^z_i$ at a representative point ($\theta = 0.4\pi, \phi = 0.99\pi$) in the d-Spiral phase. The data are obtained by performing DMRG numerics on a periodic system of $L = 36$ sites under an $h = 10^{-4}$ field along the (110) direction. As can be seen from Fig. 14, the pattern of the spin orientations are fully consistent with Eq. (63), with extracted values $f, k$, and $h$ as $f \approx -0.0936$, $k \approx -0.0928879$, and $h \approx 0.0127$. This provides evidence for the existence of the d-Spiral phase. We note that numerics have also been done for several other points in the d-Spiral phase which are all consistent with Eq. (63).

C. Numerical results

We first determine the range of the d-Spiral phase by studying the ground state energy $E(\theta, \phi)$ as a function of $\theta, \phi$. Figure 13(a) shows the second-order derivative $\partial^2 E(\theta, \phi)/\partial \theta^2$ in vertical scans by varying $\theta$ for several fixed values of $\phi$, where ED numerics are performed for a periodic system of $L = 24$ sites. The sequence of the uppermost divergent peaks in Fig. 13(a) correspond to first-order phase transitions which determine the upper boundary of the d-Spiral phase represented by the solid blue circles connected with the blue line in Fig. 13(c). To further confirm the nature of the peaks as first-order phase transitions, we have studied the finite size scaling behaviors of $\partial^2 E(\theta, \phi)/\partial \theta^2$; Figure 13(b) displays the numerical results for $\partial^2 E(\theta, \phi)/\partial \theta^2$ at $\phi = 0.95\pi$ with three different system sizes $L = 12$, 24, and 36. As is clear from Fig. 13(b), $\partial^2 E(\theta, \phi)/\partial \theta^2$ scales linearly with $L$, indicating a first-order phase transition. On the other hand, we find no divergence in $\partial^2 E(\theta, \phi)/\partial \phi^2$ when the lower boundary of the d-Spiral phase is traversed. Recall that there is a divergence in $\partial^2 E(\theta, \phi)/\partial \phi^2$ as a function of $\phi$ as discussed in Fig. 7(c), which determines the lower boundary between the d-Spiral phase and the LL1 phase shown by the solid black squares in Fig. 13(c) within the region $\phi \in [0.96\pi, \pi]$. Next we discuss the numerical evidence for the spin ordering in Eq. (63) within the four-sublattice rotated frame. Before going to that, we mention a subtlety in numerical calculations. The four symmetry breaking ground states only become exactly degenerate in the thermodynamic limit. The ground state of a finite size system can be some arbitrary linear combination of the four states, and the coefficients depend on the system size and numerical details. Because of this, random cancellations occur if the expectation values of the spin operators $\langle \vec{S}_i \rangle$ are directly computed. To circumvent this problem, we measure $\langle \vec{S}_i \rangle$ in the presence of a small field along the (110) direction, which is able to polarize the system to reside in one of the four nearly degenerate states so that the spins orient according to the pattern in Eq. (63). The value of this field should satisfy $\Delta E \ll |\mathbf{h}|L \ll E_c$, where $\Delta E$ is the finite size energy splitting among the four states, $E_c$ is the gap between the ground state multiplet and the excitations, and $|\mathbf{h}|$ is the magnitude of the applied field. Such choice of field leads to a degenerate perturbation within the ground state quartet, but no mixing is induced between the ground state subspace and the excitations.

VI. THE LL3 PHASE

In this section, we study the LL3 phase in Fig. 1, and demonstrate that the low-energy physics in this phase is described by the Luttinger liquid theory. The system exhibits a site-dependent quantization axis for the longitudinal fluctuations within the original frame as shown in Fig. 15. Recall that as discussed in Sec. II B 2, the four-sublattice rotation reveals a hidden SU(2) symmetric AFM point, i.e., the AFM3 point in Fig. 1. We will study the region close to the AFM3 point...
using again a combination of RG and symmetry analysis. Numerics provide evidence for Luttinger liquid behaviors in the entire region of the LL3 phase as shown in Fig. 2. To facilitate analysis, we work in the four-sublattice rotated frame defined by Eq. (6) throughout this section unless otherwise stated.

A. Perturbative analysis

We first remark that in the absence of $\Gamma$, there is a duality transformation for the Kitaev-Heisenberg chain as discussed in Sec. II B 2. This establishes the equivalence between the arcs $[K, \text{AFM3}]$ and $[\text{AFM1}, K]$ on the circular boundary of the half sphere in Fig. 1. Since the latter (i.e., the LL2 phase) has been shown to be described by Luttinger liquid theory in Sec. IV A, we conclude that $[K, \text{AFM3}]$ is also in a Luttinger liquid phase [50].

Next we include a nonzero $\Gamma$. The Kitaev and Gamma terms will be treated as perturbations to the SU(2)$_1$ WZW theory which describes the low-energy physics of the AFM3 point in the four-sublattice rotated frame. We perform a first-order projection of the perturbing Hamiltonian to obtain the low-energy field theory of the system. According to Eq. (7), the perturbing Hamiltonian $\Delta H''$ is

$$\Delta H'' = \sum_{\langle ij \rangle \in \text{bond}} \left[ (K + 2J)S_i^\alpha S_j^\beta + \epsilon (\gamma) \Gamma (S_i^\alpha S_j^\beta + S_i^\beta S_j^\alpha) \right].$$

(65)

Notice that all of the operators $\hat{J}_z$, $\hat{J}_k$, and $g$ are invariant under translation by two sites, whereas the $\Gamma$ term in Eq. (65) is staggered every two sites. Therefore the $\Gamma$ term vanishes after projecting to the low-energy degrees of freedom and thus has no effect. This means that at least up to first-order projection, the low-energy Hamiltonian of the $K\Gamma$ chain is of an XXZ type, having the same coupling constants as an Kitaev-Heisenberg chain. Based on this analysis, the phase diagram for fixed values of $\phi$ but changing $\theta$ in the vicinity of the AFM3 point can be derived as shown in Fig. 16. When $\theta > \theta_c$, the system flows to a strong coupling limit where an order develops, whereas when $\theta < \theta_c$, the system remains gapless. Up to first-order approximation, $\theta_c$ is equal to $\pi - \arctan(2)$ independent of $\phi$.

However, a concern at this point is whether higher-order effects will spoil the XXZ-type low-energy Hamiltonian, and in particular, whether the gapless Luttinger liquid phase in Fig. 16 is stable with respect to high-order perturbations. To resolve this question, we have performed a careful symmetry analysis. The symmetry group of the system in the four-sublattice rotated frame has been demonstrated to be $G_3 \cong D_{4d} \ltimes 4Z$ in Sec. V B. We are able to show that up to relevant and marginal couplings, the symmetry allowed terms other than the XXZ-type low-energy Hamiltonian only include the chiral term $J_z^k - J_z^k$. Since this chiral term can be eliminated by a chiral rotation [61–63], the low-energy physics remains to be of the XXZ type. The detailed symmetry analysis is included in Ref. [54]. This justifies the validity of the first-order perturbation analysis and the phase diagram in

FIG. 14. Measured expectation values of (a) $\langle S_x^j \rangle$, (b) $\langle S_y^j \rangle$, and (c) $\langle S_z^j \rangle$ as functions of $j$ under a small field $h = 10^{-4}$ along the (110) direction. The inset figures in (a) and (b) are zoom-in of the spin expectation values. DMRG numerics are performed on a system of $L = 36$ sites with periodic boundary conditions.

FIG. 15. Site-dependent quantization axes for the longitudinal fluctuations in the LL3 phase within the original frame. The black arrows denote the directions of the quantization axes, and the blue ellipses represent the transverse fluctuations. The red line represents the AFM quasi-long-range order for the longitudinal and transverse fluctuations defined in terms of the four-sublattice rotated frame. The $z$ direction in spin space is chosen to be pointing upwards, and the $y$ direction is along the chain to the right.

FIG. 16. Phase diagram in the vicinity of the AFM3 point for fixed values of $\phi$ but changing $\theta$. The critical value $\theta_c$ depends on $\phi$. 

033268-14
Fig. 16. However, we emphasize that the value of $\theta_c$ can be shifted due to high-order effects, and the actual value of $\theta_c$ is a function of $\phi$.

In the LL3 phase, based on the above analysis, the quantization axis for the longitudinal fluctuations in the four-sublattice rotated frame is along the $z$ direction. Notice that by performing the inverse of the four-sublattice rotation defined in Eq. (6), the $z$ direction becomes staggered in the original frame, hence the quantization axes in the LL3 phase are drawn in a staggered manner in Fig. 15. On the other hand, we emphasize that the quantization axes in Fig. 15 are not precise, since they can acquire site-dependent distortions due to the renormalization effects of the spin operators along the RG flow similar to the situation in Sec. III C.

We also note that the ordered phase in Fig. 16 is an Néel order along $z$ direction, which is in the four-sublattice rotation frame. As can be checked by performing the inverse of the four-sublattice rotation, the Neél-$z$ order becomes an FM-$z$ order in the original frame. But this is not accurate due to the possible distortions of the quantization axes. To identify the precise direction of the ordering, we first figure out the unbroken symmetries of the Néel-$z$ order in the four-sublattice rotated frame, and then solve the most general form of the spin orientations which are invariant under the unbroken symmetry group.

The full symmetry group of the model in the four-sublattice rotated frame is given by $G_3$ in Eq. (60). As can be easily checked, the unbroken symmetry group $H_3$ corresponding to the Neél-$z$ order is

$$H_3 = \left\{ R(\hat{y}, \pi)T_0I, \, TR\left(\hat{z}, -\frac{\pi}{2}\right)T_a \right\}. \tag{66}$$

Since $T_{ad} = (TR(\hat{z}, -\frac{\pi}{2})T_a)^4$ is an unbroken symmetry operation, we will consider spins in a unit cell in what follows where all site indices should be understood as modulo four. The most general spin alignments which are invariant under the group $H_3$ in Eq. (66) can then be solved as

$$\vec{S}_1 = (-a, a, -b)^T, \quad \vec{S}_2 = (-a, -a, b)^T, \quad \vec{S}_3 = (a, -a, -b)^T, \quad \vec{S}_4 = (a, a, b)^T, \tag{67}$$

in which $a$ and $b$ are two parameters depending on the values of $K$, $\Gamma$, and $J$. Performing the inverse of the four-sublattice rotation defined in Eq. (6), the spin ordering in the original frame can be determined as

$$\vec{S}_1^{(0)} = (a, a, b)^T, \tag{68}$$

which is an FM order along the $(a, a, b)$ direction, providing another understanding to the FM phase in Fig. 1.

B. Numerical results

The Luttinger parameter $K$ can be extracted numerically using the same method as Sec. III D. DMRG numerics are performed to calculate the energy density on an open system of $L = 96$ sites. We have studied the Luttinger parameter in the entire LL3 phase and the results are shown in Fig. 2. On the right-hand side of the phase boundary between the LL3 and $D_3$-breaking phases, no Luttinger parameter can be extracted, and in fact, the transition line in Fig. 1 between these two phases is determined in this way. On the other hand, as discussed in Sec. VI A, the phase transition between the LL3 and FM phases is second-order. Since a gap $E_g \sim e^{-\text{const}/|\theta\varepsilon|}$ opens exponentially slowly in the FM phase close to the transition line [44], the Luttinger liquid behaviors percolate into the FM phase in a finite size system, which smeared the phase transition as can be seen from Fig. 2.

VII. THE LL4 AND $D_3$-BREAKING I, II PHASES

In this section, we study the LL4 and the $D_3$-breaking I, II phases in Fig. 1. In the LL4 phase, the system exhibits a site-dependent quantization axis for the longitudinal fluctuations within the rotated frame as shown in Fig. 17. In the $D_3$-breaking I, II phases, the spin orientations have six-site periodicities within the original frame as shown in Fig. 18. To facilitate analysis, we work in the six-sublattice rotated frame throughout this section unless otherwise stated.

The strategy is to separate the Hamiltonian into two parts, where one part is of the easy-plane XXZ type, and the other part is taken as a perturbation. We demonstrate that the first-order projection of the perturbation term to the low-energy degrees of freedom remains to be of the XXZ type, indicating that there exists a region of Luttinger liquid which is stable against the perturbation.

However, the Luttinger parameter diverges as $J \rightarrow 0$, and higher-order terms eventually become relevant driving the system into an ordered phase. As discussed in Sec. III B, the symmetry group in the six-sublattice rotated frame is
isomorphic to $D_{3d} \times 3\mathbb{Z}$. We demonstrate that there are two types of orders both having sixfold degenerate ground states. The symmetry breaking patterns are $D_{3d} \rightarrow Z_2^{(1)}$ and $D_{3d} \rightarrow Z_2^{(II)}$ in the two ordered phases, respectively, where $Z_2^{(1)}$ and $Z_2^{(II)}$ are two different $Z_2$ groups. Since $D_{3d}/Z_2 \cong D_3$, both ordered phases break $D_3$ symmetry (albeit different $D_3$ groups), and the two phases are named as $D_3$-breaking I and $D_3$-breaking II. The regions occupied by these two different $D_3$-breaking orders are determined by a classical analysis discussed in Sec. VII B 3. On the other hand, when $|\lambda|$ becomes large, the system is driven into a Néel ordered phase along the (111) direction in the six-sublattice rotated frame, which corresponds to the FM phase in the original frame in Fig. 1.

Finally in Sec. VII C, we present and discuss DMRG numerical results, which provide evidence for the existence of the LL4 and the two $D_3$-breaking phases.

A. Perturbative Luttinger liquid analysis and the LL4 phase

We will perform a perturbative analysis in a neighborhood of the FM2 point in the lower hemisphere. Thus $\Gamma$, $K > 0$, and $J < 0$. Performing the following two-sublattice rotation to the six-sublattice rotated spin operators $S_{ij}^{\nu}$’s,

$$
S_{ij}^{\nu} = (-)^{i} \left( - \frac{1}{\sqrt{6}} S_{ij}^{x} + \sqrt{\frac{2}{3}} S_{ij}^{y} - \frac{1}{\sqrt{6}} S_{ij}^{z} \right),
$$

$$
S_{j}^{\nu} = (-)^{j} \left( - \frac{1}{\sqrt{2}} S_{j}^{x} + \frac{1}{\sqrt{2}} S_{j}^{y} \right),
$$

$$
S_{j}^{z} = \frac{1}{\sqrt{3}} S_{j}^{x} + \frac{1}{\sqrt{3}} S_{j}^{y} + \frac{1}{\sqrt{3}} S_{j}^{z},
$$

the Hamiltonian in Eq. (5) becomes

$$
\mathcal{H} = \mathcal{H}_{XXZ} + \Delta H + \Delta H^{(2)},
$$

in which

$$
\mathcal{H}_{XXZ} = \sum_{j} \left[ \Gamma \left( S_{ij}^{x} S_{j+1}^{x} + S_{ij}^{y} S_{j+1}^{y} \right) + (\Gamma + J) S_{ij}^{z} S_{j+1}^{z} \right],
$$

$$
\Delta H = \sum_{i=1,2,3} \sum_{n} \Delta H_{i+3n,i+3n}^{(2)} + \Delta H_{i+3n,i+3n}^{(2)},
$$

$$
\Delta H^{(2)} = \sum_{i=1,2,3} \sum_{n} \Delta H_{i+3n,i+3n}^{(2)},
$$

where

$$
\Delta H_{i+3n,2+3n} = \frac{1}{2} J \left( S_{i+3n}^{x} S_{i+3n}^{x} - S_{i+3n}^{y} S_{i+3n}^{y} \right) + \sqrt{\frac{2}{3}} J \left( S_{i+3n}^{y} S_{i+3n}^{y} + S_{i+3n}^{x} S_{i+3n}^{x} \right),
$$

$$
\Delta H_{2+3n,3+3n} = \frac{1}{2} J \left( S_{2+3n}^{x} S_{2+3n}^{x} - S_{2+3n}^{y} S_{2+3n}^{y} \right) - \sqrt{\frac{2}{3}} J \left( S_{2+3n}^{y} S_{2+3n}^{y} + S_{2+3n}^{x} S_{2+3n}^{x} \right),
$$

$$
\Delta H_{3+3n,4+3n} = J \left( S_{3+3n}^{x} S_{3+3n}^{x} - S_{3+3n}^{y} S_{3+3n}^{y} \right),
$$

and

$$
\Delta H_{1+3n,2+3n}^{(2)} = (\Gamma - K) S_{1+3n}^{x} S_{2+3n}^{x} + S_{1+3n}^{y} S_{2+3n}^{y},
$$

$$
\Delta H_{2+3n,3+3n}^{(2)} = (\Gamma - K) S_{2+3n}^{x} S_{3+3n}^{x} + S_{2+3n}^{y} S_{3+3n}^{y},
$$

$$
\Delta H_{3+3n,4+3n}^{(2)} = (\Gamma - K) S_{3+3n}^{x} S_{4+3n}^{x} + S_{3+3n}^{y} S_{4+3n}^{y}. \tag{73}
$$

Notice that the $S_{ij}^{\nu}$’s in $\Delta H^{(2)}$ can be written in terms of $S_{ij}^{\nu}$ via Eq. (69). We note that the purpose of this additional two-sublattice rotation is to make the transverse directions to have an AFM coupling in $H_{XXZ}$.

Clearly, $H_{XXZ}$ corresponds to an easy-plane XXZ chain when $J < 0$, $\Gamma > 0$. The low-energy theory is described by the Luttinger liquid Hamiltonian in Eq. (27), and the Luttinger parameter $\kappa$ is known to be [64]

$$
\kappa = \frac{\pi}{2 \arccos \left( \frac{J_{1}}{J} \right)}, \tag{74}
$$

in which $J_{1} = \Gamma - |J|$ and $J_{||} = \Gamma$.

Next, we add $\Delta H$ and $\Delta H^{(2)}$ as perturbations. Let’s first consider $\Delta H^{(2)}$. In the Luttinger liquid phase, the continuum limit can be taken at low energies. To avoid the staggered sign, we enlarge the unit cell to six sites, and consider the following sum:

$$
\Delta H^{(2)} = (\Gamma - K) \sum_{n} \left( \Delta H_{n}^{(2),a} + \Delta H_{n}^{(2),b} \right), \tag{75}
$$

in which

$$
\Delta H_{n}^{(2),a} = S_{n}^{x} S_{n+3}^{x} + S_{n}^{y} S_{n+3}^{y} + S_{n}^{x} S_{n+3}^{x} + S_{n}^{y} S_{n+3}^{y} + S_{n}^{x} S_{n+3}^{x} + S_{n}^{y} S_{n+3}^{y},
$$

$$
\Delta H_{n}^{(2),b} = S_{n}^{x} S_{n+3}^{x} + S_{n}^{y} S_{n+3}^{y} + S_{n}^{x} S_{n+3}^{x} + S_{n}^{y} S_{n+3}^{y} + S_{n}^{x} S_{n+3}^{x} + S_{n}^{y} S_{n+3}^{y}. \tag{76}
$$

The first-order effect of $\Delta H^{(2)}$ can be obtained by projecting $\Delta H^{(2)}$ to the low-energy degrees of freedom using the following Abelian bosonization formula for the spin operators [44],

$$
S_{i}^{c}(x) = - \frac{1}{\sqrt{\pi}} \nabla \phi(x) + \text{const.} \frac{1}{a} (-)^{x} \cos(2 \sqrt{\pi} \phi(x)),
$$

$$
S_{i}^{c}(x) = \text{const.} \frac{1}{\sqrt{\pi}} e^{i \pi \phi(x)} \left[ (-)^{x} \cos(2 \sqrt{\pi} \phi(x)) \right]. \tag{77}
$$

In which $a$ is the lattice constant, $n$ is the lattice site number, and $x = na$. We note that the first-order perturbation projection can be figured out without even carrying out any calculation. Since different sites are smeared out in the continuum limit, both $\Delta H_{n}^{(2),a}$ and $\Delta H_{n}^{(2),b}$ become SU(2) symmetric $\sim S_{i}^{c} \cdot S_{i}^{c} + S_{i}^{a} \cdot S_{i}^{a}$. As a result, the effect of $\Delta H^{(2)}$ is to shift the values of $J_{i}$ and $J_{\perp}$, as

$$
J_{||} = \Gamma - |J| - \frac{1}{2} (\Gamma - K),
$$

$$
J_{\perp} = \Gamma - \frac{1}{2} (\Gamma - K). \tag{78}
$$

Since we still have $|J_{i}| < |J_{\perp}|$ when $\Delta H^{(2)}$ is included, the system remains to be gapless at least for $|\Delta| \ll 1$ where $\Delta = (K - \Gamma)/\Gamma$. Of course, the Luttinger parameter is renormalized due to $\Delta H^{(2)}$.

Next we consider the effects of $\Delta H$. Again, the first-order effect of $\Delta H$ can be obtained by projecting $\Delta H$ to the low-energy degrees of freedom using Eq. (77). In fact, it can be observed that the projection vanishes without even carrying
out any calculation. From Eq. (72), we obtain
\[ \Delta H_{1+6,2+6} + \Delta H_{4+6,3+6} + \Delta H_{5+6,6+6} = -\frac{1}{2} J (\mathcal{F}_{1+6} - 2 \mathcal{F}_{3+6} + \mathcal{F}_{5+6}) \]
\[ + \frac{\sqrt{3}}{2} J (\mathcal{G}_{1+6} - \mathcal{G}_{5+6}), \]
(79)
in which
\[ \mathcal{F}_i = S_i^x S_{i+1}^x - S_i^y S_{i+1}^y, \]
\[ \mathcal{G}_i = S_i^x S_{i+1}^y + S_i^y S_{i+1}^x. \]
(80)
In the continuum limit, Eq. (79) consists of total derivatives as can be seen by Taylor expanding \( \mathcal{F} \) and \( \mathcal{G} \), which vanish in the Hamiltonian after the integration \( \int dx \). Similar analysis can be performed on the other three terms \( \Delta H_{1+6,2+6} + \Delta H_{4+6,3+6} + \Delta H_{5+6,6+6} \). Hence we conclude that the projection of \( \Delta H \) onto the Luttinger liquid degrees of freedom vanishes, and the system should remain in the Luttinger liquid phase up to first-order in \( J \).

However, the above analysis of first-order projection cannot be trusted if higher-order effects are included. Since \( K \) diverges as \( J \to 0 \), higher-order terms may become relevant for small enough \( J \). Denote \( J^{\alpha} \) and \( N^{\alpha} \) as the uniform and staggered parts of the spin operators \( S^{\alpha} \), respectively, which, according to Eq. (77), are defined as
\[ J^{\alpha} = \frac{1}{a} \cos(\sqrt{4\pi} \varphi) \cos(\sqrt{\pi} \theta), \]
\[ J^{\gamma} = \frac{1}{a} \cos(\sqrt{4\pi} \varphi) \sin(\sqrt{\pi} \theta), \]
\[ J^{\zeta} = -\frac{1}{\sqrt{\pi}} \nabla \varphi, \]
(81)
and
\[ N^{\alpha} = \frac{1}{a} \cos(\sqrt{\pi} \theta), \]
\[ N^{\gamma} = \frac{1}{a} \sin(\sqrt{\pi} \theta), \]
\[ N^{\zeta} = \frac{1}{a} \cos(\sqrt{4\pi} \varphi). \]
(82)
Since the scaling dimension of \( N^{\alpha} = (N^{\alpha} \pm iN^{\gamma}) / 4 \) is 1/(4\( K \)), the operators involving powers of \( N^{\alpha} \) become relevant for sufficiently small \( J \). On the other hand, since \( N^{\gamma} \) has scaling dimension equal to \( K \), the operators involving \( N^{\gamma} \) become relevant when \( K \) is small enough. Hence, in what follows, we will consider terms only involving \( N^{\alpha} \) for \( x = \gamma, \zeta \), which should be able to capture the spin orderings for both small and large values of \( J \).

Next we perform a symmetry analysis to figure out what terms are allowed in the low-energy theory. In the rotated basis defined via Eq. (69), the generators of the symmetry group \( G_1 \) in Eq. (20) become
\[ R'_x T_n = U_2 R_3 T_n U_2^{-1}, \]
\[ R'_z I = U_2 R_4 I U_2^{-1}, \]
(83)
where \( U_2 \) is equal to \( \Pi_2 R_2(\varphi', \pi R) \) which gives the transformation in Eq. (69). It is straightforward to verify that
\[ R'_x = R(\varphi', -\frac{\pi}{2}), \quad R'_y = R(\varphi', \pi), \]
and \( R'_z = R(\varphi, \pi) \). Under the symmetries in Eq. (83), the transformation properties of \( N^{\alpha} \) are
\[ T(N^{\alpha} N^{-\alpha}) = (N^{\alpha}, N^{-\alpha})(-\tau_2), \]
\[ R'_x T_n (N^{\alpha} N^{-\alpha}) (R'_x T_n)^{-1} = (N^{\alpha} N^{-\alpha}) \left( \frac{1}{2} \tau_0 - \frac{\sqrt{3}}{2} \tau_1 \right), \]
\[ R'_z I (N^{\alpha} N^{-\alpha}) (R'_z)^{-1} = (N^{\alpha} N^{-\alpha})(-\tau_1), \]
(84)
and
\[ T N^{\alpha} I^{-1} = -N^{\alpha}, \quad (R'_x T_n) N^{\alpha} (R'_x)^{-1} = -N^{\alpha}, \]
\[ (R'_z I) N^{\alpha} (R'_z)^{-1} = -N^{\alpha}, \]
(85)
in which \( \tau_\alpha (\alpha = 1, 2, 3) \) are the three Pauli matrices, and \( \tau_0 \) is the \( 2 \times 2 \) identity matrix. Therefore we see that the following terms are allowed in the low-energy Hamiltonian:
\[ (N^{\alpha} \pm iN^{\gamma}) \cos(6\sqrt{\pi} \theta), \]
(86)
where \( n > 0, n \in \mathbb{Z} \).

At large \( K \), the symmetry allowed operator with the smallest scaling dimension \( (\varphi^2, K) \) is
\[ \sim (J^3 [N^{\alpha} \theta + (N^{-\alpha}) \theta]), \]
(87)
which is \( \sim J^3 \cos(6\sqrt{\pi} \theta) \) after bosonization. Notice that this term can only appear at the level of third-order perturbations, hence the coupling should be proportional to \( J^3 \). When \( K > 4.5, \cos(6\sqrt{\pi} \theta) \) becomes relevant. According to Eq. (74), the value of \( J \) which has the critical \( K \) value \( (\approx 4.5) \) is
\[ J_{c1}(\Delta) = -\Gamma \left( 1 + \frac{\Delta}{3} \right) \left[ 1 - \cos(\frac{\pi}{3}) \right]. \]
(88)
When \( \Delta = 0 \) (i.e., \( \phi = 0.25\pi \)), the corresponding \( \theta_{c1} \) determined from Eq. (88) is 0.514\( \pi \). Of course, the value of \( J_{c1}(\Delta) \) in Eq. (88) is not accurate due to higher-order effects. Based on the above analysis, we see that the Luttinger liquid is stable only when \( |J| > |J_{c1}(\Delta)| \) for a fixed value of \( \Delta \).

On the other hand, the above analysis applies only to the region of a small \( |J| \). By increasing \( |J| \), we note that the term \( (N^{\alpha})^2 \sim \cos(4\sqrt{\pi} \theta) \) eventually has a smaller dimension than \( \cos(6\sqrt{\pi} \theta) \). When the Luttinger parameter \( K \) is smaller than 1/2, \( (N^{\alpha})^2 \) becomes relevant since its scaling dimension is \( 4K \). Hence there exists another critical value \( |J_{c2}(\Delta)| \) above which the Luttinger liquid becomes unstable again. In conclusion, a Luttinger liquid can be stabilized in an intermediate range \( |J_{c1}(\Delta)| < |J| < |J_{c2}(\Delta)| \), i.e., \( J_{c2}(\Delta) < |J| < J_{c1}(\Delta) \).

B. The \( D_3 \)-breaking phase

1. The strong coupling limit for \( |J| > |J_{c1} | \)

We will figure out the spin orders corresponding to the above mentioned two strong coupling limits when \( |J| < |J_{c1}| \) and \( |J| > |J_{c2}| \). Let’s first consider \( |J| < |J_{c1}(\Delta)| \). The term \( \lambda \cos(6\sqrt{\pi} \theta) \) is minimized at the following values of the angle \( \theta \),
\[ \theta_n^{(i)} = \frac{(2n + 1)\sqrt{\pi}}{6}, \quad \lambda > 0, \]
\[ \theta_n^{(ii)} = \frac{n\sqrt{\pi}}{3}, \quad \lambda < 0, \]
(89)
in which \( \lambda \) is the coupling constant in the term \( \lambda \cos(6\sqrt{\pi} \theta) \), and \( 0 \leq n \leq 5, \, n \in \mathbb{Z} \). Notice that the system is sixfold degenerate regardless of the sign of \( \lambda \). Naively, according to Eq. (77), the spins exhibit a Néel ordering in the \( x'y' \) plane given by
\[
\vec{S}_y' = (-)^n \mathbf{N}_1 \left( \cos(\sqrt{\pi} \theta) \right), \, \sin(\sqrt{\pi} \theta), \, 0, \quad (90)
\]
in which \( \mathbf{N}_1 \) is the magnitude of the ordering.

However, we note that the spin orders in Eq. (90) are not precise. This is because there can be U(1) breaking coefficients in the Abelian bosonization formula Eq. (77) due to the renormalization effects in the high energy region along the RG flow, which is similar to the case encountered in Eq. (10) as discussed in details in Ref. [53]. As a result, the Abelian bosonization formula (77) should only respect the discrete lattice symmetry, not the emergent U(1) symmetry at low energies. Taking this into account, the true spin orientations will be distorted with respect to those in Eq. (90) due to the U(1) breaking coefficients. To figure out the correct pattern of the spin orientations, we first determine the symmetry breaking pattern corresponding to the spin ordering in Eq. (90), and then solve the most general form of the spin orderings which is consistent with the identified symmetry breaking. This approach is similar as the one used in Sec. VI A to discuss the FM phase based on the RG analysis in the vicinity of the AFM3 point.

When \( \lambda > 0 \), we choose a representative spin configuration corresponding to \( n = 1 \) in Eq.(90). As can be seen from Eq. (90), this is a Néel order along \( y' \) direction. As can be easily checked, the Néel-y' configuration is invariant under \( T T_{3a} \) and \( R'_I \). Hence the little group of the Néel-y' order is
\[
H^{(1)} = \langle TT_{3a}, R'_I \rangle, \quad (91)
\]
which can be rewritten as
\[
H^{(1)} = Z^{(1)}_2 \times 3Z,
\]
where \( Z^{(1)}_2 = \langle R'_I \rangle \), and \( 3Z = \langle TT_{3a} \rangle \). Recall that the symmetry group of the Hamiltonian \( H' \) in Eq. (70) is \( G'_1 = \langle T, R'_a T_a, R'_I \rangle \), which can be rewritten as
\[
G'_1 = D_{3d} \times 3Z,
\]
where \( D_{3d} = \langle T, R'_a T_a, R'_I \rangle \) mod \( TT_{3a} \), and \( 3Z = \langle TT_{3a} \rangle \). Therefore, by taking the quotient of \( TT_{3a} \), we conclude that the symmetry breaking pattern is
\[
D_{3d} \to Z^{(1)}_2.
\]
Notice that since \( |D_{3d}/Z^{(1)}_2| = 6 \), the ground states are sixfold degenerate. This order is named as \( D_3 \)-breaking I since the broken symmetry group \( D_{3d}/Z^{(1)}_2 \) is isomorphic to \( D_3 \).

Next, we work out the most general form of the spin ordering which is invariant under \( H^{(1)} \). The invariance under \( TT_{3a} \) clearly requires
\[
\tilde{S}^{(1)}_{1+3} = -\tilde{S}^{(1)}_{y'}.
\]
As can be checked, further requiring the invariance under \( R'_I \), the spin alignments are constrained to be
\[
\begin{align*}
\tilde{S}^{(1)}_{1+3} &= (-)^n \mathbf{N}_1' (x', y', z')^T, \\
\tilde{S}^{(1)}_{2+3} &= (-)^n \mathbf{N}_1' (0, 1, 0)^T, \\
\tilde{S}^{(1)}_{3+3} &= (-)^n \mathbf{N}_1' (-x', y', -z')^T,
\end{align*}
\]
(96)
in which \( x'^2 + y'^2 + z'^2 = 1 \). The other five degenerate spin configurations can be obtained by performing the operations in the equivalent classes in \( D_{3d}/Z^{(1)}_2 \) to the spin ordering in Eq. (96).

It is interesting to work out the spin alignments in the six-sublattice rotated frame by performing the inverse of the transformation defined in Eq. (69). The result is
\[
\begin{align*}
\tilde{S}^{(1)}_{1+3} &= N^{(1)}_1 (x, y, z)^T, \\
\tilde{S}^{(1)}_{2+3} &= N^{(1)}_1 \left( \frac{1}{\sqrt{2}}, 0, 1 \right)^T, \\
\tilde{S}^{(1)}_{3+3} &= N^{(1)}_1 (-z, -y, -x)^T, \\
\tilde{S}^{(1)}_{0+3} &= N^{(1)}_1 (x, y, z)^T, \\
\tilde{S}^{(1)}_{1+3} &= N^{(1)}_1 (y, x, z)^T, \\
\tilde{S}^{(1)}_{2+3} &= N^{(1)}_1 (-z, -y, -x)^T, \\
\tilde{S}^{(1)}_{3+3} &= N^{(1)}_1 (-x, -y, -z)^T.
\end{align*}
\]
(97)
in which \( x, y, z \) can be expressed through \( x', y', z' \) using Eq. (69). Define \( \tilde{S}^{(1)}_c = \frac{1}{\sqrt{6}} \sqrt{S^{(1)}_{0+3} + S^{(1)}_{1+3} + S^{(1)}_{2+3}} \) to be the “center of mass” direction for the three spins in a unit cell in the six-sublattice rotated frame. Then according to Eq. (97), it is clear that \( \tilde{S}^{(1)}_c \) is along the \( (-1, 0, 1) \) direction. The “center of mass” directions in the six degenerate ground states are represented as the six red circles as shown in Fig. 19. Furthermore, by performing the inverse of the six-sublattice rotation defined in Eq. (4), the spin ordering in the original frame can be worked out as
\[
\begin{align*}
\tilde{S}^{(0)}_{1+6} &= N^{(1)}_1 (x, y, z)^T, \\
\tilde{S}^{(0)}_{2+6} &= N^{(1)}_1 \left( \frac{1}{\sqrt{2}}, -\frac{1}{\sqrt{2}}, 0 \right)^T, \\
\tilde{S}^{(0)}_{3+6} &= N^{(1)}_1 (y, x, z)^T, \\
\tilde{S}^{(0)}_{4+6} &= N^{(1)}_1 (-x, -y, -z)^T, \\
\tilde{S}^{(0)}_{5+6} &= N^{(1)}_1 (-y, -x, -z)^T, \\
\tilde{S}^{(0)}_{6+6} &= N^{(1)}_1 (x, y, z)^T.
\end{align*}
\]
(98)
in which the superscript (0) is used to denote the original frame. A plot of the spin orientations in Eq. (98) is shown in Fig. 18(a) where the unnormalized parameters are chosen as \( x = -1, y = 0, \) and \( z = 1 \).

A similar analysis can be performed to the case \( \lambda < 0 \). Choosing \( n = 0 \) in \( \theta_1^{(1)} \), we see that the system has a Néel ordering along the \( x \) direction. It can be shown that the little group of the Néel-\( x \) configuration is

\[
H^{(1)} = (TT_{3a}, TR_{1}I).
\]

This time, the symmetry breaking pattern is

\[
D_{3d} \rightarrow Z_2^{(1)} ,
\]

in which \( Z_2^{(1)} = (TR_{1}I) \). The most general spin alignments invariant under \( H^{(1)} \) are

\[
\begin{align*}
\tilde{S}_{1+3n}^{(1)} &= (-)^n N_{\perp}^{(1)} (a', b', c')^T, \\
\tilde{S}_{2+3n}^{(1)} &= (-)^n N_{\perp}^{(1)} (m', 0, n')^T, \\
\tilde{S}_{3+3n}^{(1)} &= (-)^n N_{\perp}^{(1)} (a', -b', c')^T,
\end{align*}
\]

in which \( a'^2 + b'^2 + c'^2 = 1, m'^2 + n'^2 = 1 \). We note that the ground states are again sixfold degenerate, and the spin orientations in the other five degenerate states can be obtained by performing the operations in the equivalent classes in \( D_{3d}/Z_2^{(1)} \) to the above spin configuration. This order is named as \( D_3 \)-breaking II since the broken symmetry group \( D_{3d}/Z_2^{(1)} \) is isomorphic to \( D_3 \). We emphasize that although the broken symmetry is again isomorphic to \( D_3 \), it is a different \( D_3 \) group compared with the \( D_3 \)-breaking I case.

Similar with the \( D_3 \)-breaking I case, the spin alignments in the \( D_3 \)-breaking II phase in the six-sublattice rotated frame can be determined as

\[
\begin{align*}
\tilde{S}_{1+3n}^{(1)} &= N_{\perp}^{(1)} (a, b, c)^T, \\
\tilde{S}_{2+3n}^{(1)} &= N_{\perp}^{(1)} (m, n, m)^T, \\
\tilde{S}_{3+3n}^{(1)} &= N_{\perp}^{(1)} (c, b, a)^T,
\end{align*}
\]

in which \( a, b, c, m, n \) can be expressed through \( a', b', c', m', n' \) using Eq. (69). By performing the classical analysis discussed in Sec. VII B 3, we find that \( a, b, c, m, n \) approach 1, -1, 1, -1, 1, respectively, in the limit \( J \rightarrow 0 \) for fixed \( \Delta \neq 0 \). Therefore, when \( J \rightarrow 0 \), the “center of mass” direction of the three spins in a unit cell defined as

\[
\tilde{S}_{c}^{(1)} = \frac{1}{\sqrt{3}} (\tilde{S}_{1+3n}^{(1)} + \tilde{S}_{2+3n}^{(1)} + \tilde{S}_{3+3n}^{(1)})
\]

is along the \( (1, 1, 1) \) direction. The \( \tilde{S}_{c}^{(1)} \)’s in the six degenerate ground states when \( J \rightarrow 0 \) are represented as the six blue circles as shown in Fig. 19. We also note that the corresponding spin orientations in the original frame are

\[
\begin{align*}
\tilde{S}_{1+6n}^{(0), (1)} &= N_{\perp}^{(1)} (a, b, c)^T, \\
\tilde{S}_{2+6n}^{(0), (1)} &= N_{\perp}^{(1)} (-m, -m, -n)^T, \\
\tilde{S}_{3+6n}^{(0), (1)} &= N_{\perp}^{(1)} (b, a, c)^T, \\
\tilde{S}_{4+6n}^{(0), (1)} &= N_{\perp}^{(1)} (-b, -a, -c)^T, \\
\tilde{S}_{5+6n}^{(0), (1)} &= N_{\perp}^{(1)} (m, m, n)^T, \\
\tilde{S}_{6+6n}^{(0), (1)} &= N_{\perp}^{(1)} (-a, -b, -c)^T.
\end{align*}
\]

A plot of the spin orientations in Eq. (103) is shown in Fig. 18(b) where the unnormalized parameters are chosen as \( a = -b = c = m = -n = 1 \).

Bases on the above analysis, we see that when \( \theta < \theta_1^{(1)}(\phi) \), \( D_3 \)-breaking orders are developed, where there are two types of possible orders denoted as \( D_3 \)-breaking I and \( D_3 \)-breaking II depending on the sign of the coupling constants. The determination of the sign of the coupling constant requires a third-order perturbation. We will not perform such a difficult calculation of third-order perturbation, but turn to a classical analysis in the \( D_{3d} \)-breaking phase which will be discussed in Sec. VII B 3, where it is verified that the region for \( \theta < \theta_1^{(1)}(\phi) \) can be divided into two subregions numbered by “I” and “II”, which have \( D_3 \)-breaking I and \( D_3 \)-breaking II orders correspondingly. The solid lines separating the two \( D_3 \)-breaking phases in Fig. 1 are determined from such classical analysis.

We also note that the coupling constant \( \sim J^3 \) is very small when \( \theta < \theta_1^{(1)}(\phi) \). Hence, from an RG point of view, the system has to flow a very long time to develop such order. This means that a very large system size is required to observe the \( D_3 \)-breaking orders, making the detection of the orders very difficult numerically. In numerics, we are not able to find a clear evidence for the sixfold ground degeneracy in either of the two “\( D_3 \)-breaking” phases. Since calculating the energies of several excited states can only be performed for rather small system sizes, the above mentioned strong finite size fact is possibly the reason for the failure of identifying the degeneracy.

2. \( O_h \rightarrow D_4 \) as part of the \( D_3 \)-breaking II phase

In this section, we remark that the \( O_h \rightarrow D_4 \) phase on the equator in Fig. 1 is actually part of the \( D_3 \)-breaking II phase.

To see this, first notice that the representative elements of different equivalent classes in \( O_h/D_4 \) can be chosen such that they form the group \( D_3 \), which means that the broken symmetries of the “\( O_h \rightarrow D_4 \)” phase can be chosen as the \( D_3 \) group. Secondly, notice that the unbroken symmetry group \( Z_2^{(1)} = (TR_{1}I) \) in the \( D_3 \)-breaking II phase is a subgroup of \( D_4 \). As discussed in Ref. [53], the spins align along \( \pm \hat{a} \) directions (\( \alpha = x, y, z \)) in the six degenerate ground states in the “\( O_h \rightarrow D_4 \)” phase within the six-sublattice rotated frame. In particular, the explicit form of the unbroken \( D_4 \) group for the ground state in which the spins align along the \( y \) direction is \( \langle (R_{y}T_{a})^{-1}R(\hat{z}, \pi)R_{y}IR(\hat{z}, \pi)(R_{y}T_{a})^{-1}, TR_{1}I/T_{a} \rangle \) (see Ref. [53]), which contains the group \( Z_2^{(1)} \). Therefore, by combining these two observations, we see that when a nonzero \( J \) is turned on, the full symmetry group of the Hamiltonian reduces from \( O_h \) to \( D_{3d} \), and concomitantly, the unbroken symmetry group reduces from \( D_4 \) to \( Z_2^{(1)} \). The reductions are coordinated in such a manner that the broken symmetries remain the same, hence the system should be viewed as residing in the same phase.

To further validate the above analysis, notice that the spin alignments in Eq. (102) transform into the following pattern under the operation \( (R_{y}T_{a})^{-1}R(\hat{z}, \pi)R_{y}IR(\hat{z}, \pi)(R_{y}T_{a})^{-1}; \)

\[
\begin{align*}
\tilde{S}_1 &\rightarrow (-a, b, c)^T, \\
\tilde{S}_2 &\rightarrow (-m, n, m)^T, \\
\tilde{S}_3 &\rightarrow (-c, b, a)^T.
\end{align*}
\]
Hence, requiring Eq. (102) to be invariant under $(R_\alpha T_\alpha)^{-1} R(\hat{\xi}, \pi) R_\alpha I R(\hat{\xi}, \pi)(R_\alpha T_\alpha)^{-1}$ in addition to $TR_\alpha I$, we obtain $a = c = m = 0$. Thus the spins in Eq. (104) are exactly along the $y$ direction, which is the spin alignments in the $O_h \rightarrow D_4$ phase. This shows that the transition of the spin alignments from the $D_3$-breaking II phase to the $O_h \rightarrow D_4$ phase is smooth, hence they should be viewed as the same phase.

3. Classical analysis

The classical analysis is the saddle point approximation in the spin path integral formalism which is valid in the large-$S$ limit, where $S$ is the spin value. In what follows, we neglect the quantum fluctuations of the spins and approximate them as classical three-vectors,

$$\vec{S}_i = S\vec{h}_i,$$

in which $S$ is the spin magnitude, $\vec{h}_i = (x_i, y_i, z_i)^T$ is a unit vector.

Absorbing $S^2$ into a redefinition of $\Gamma$, $K$, and $J$ by defining

$$\Gamma' = \Gamma S^2, \quad K' = KS^2, \quad J' = JS^2,$$

and introducing the Lagrange multipliers $\{\lambda_i\}_{1 \leq i \leq 3}$ to impose the constraints $x_i^2 + y_i^2 + z_i^2 = 1$, the energy per unit cell in the six-sublattice rotated frame becomes

$$F = -(K' + J')x_1x_2 - \Gamma'(y_1y_2 + z_1z_2) - J'(y_1z_2 + y_1z_2)
- (K' + J')z_1z_2 - \Gamma'(x_1x_2 + y_1y_2) - J'(x_1y_2 + y_1y_2)
- (K' + J')y_1y_2 - \Gamma'(z_1z_2 + x_1x_2) - J'(z_1x_2 + x_1z_2)
- \sum_{i=1}^{3} \frac{1}{2} \lambda_i (x_i^2 + y_i^2 + z_i^2 - 1),$$

in which the free energy corresponding to a general spin-$S$ KHF chain is considered. We have numerically studied the minimization of the classical free energy, and verified that the solution of Eq. (96) (Eq. (101)) corresponds to the global minimum of the free energy in the range denoted by the $D_3$-breaking I ($D_3$-breaking II) phase in Fig. 20.

4. The strong coupling limit for $|J| > |J_{c1}|$

The above analysis completes the discussion for the strong coupling limit in the region $|J| < |J_{c2}(\Delta)|$. Next we identify the order parameter region $|J| > |J_{c2}(\Delta)|$. When $\cos(\sqrt{\pi} \theta)$ becomes relevant, $\phi_n$ orders at $\sqrt{(2n + 1)/4} \phi$ or $n\sqrt{\pi}/2$ depending on the sign of the coupling constant. According to the bosonization formula in Eq. (77), the system develops a Néel ordering along $\zeta$ direction. Performing the inverse of the transformation in Eq. (69), it corresponds to a Néel-$\vec{h}_n$ order in the six-sublattice rotated frame, where $\vec{h}_n$ is the unit vector along the (111) direction. As discussed in Sec. III C, by taking into account the distortions of the quantization axes in the bosonization formula and performing the inverse of the six-sublattice rotation, the Néel-$\vec{h}_n$ ordering corresponds to an FM spin order in the original frame. Thus we conclude that the system should transit from the LL4 phase to the FM phase by increasing the magnitude of $J$ where $J < 0$.

FIG. 20. Classical phase diagram in the vicinity of the FM2 point for negative $J$.

We can also make a tree-level estimation on the value of $J_{c2}$. As can be seen from Eq. (71), the anisotropy of the $H_{XXXX} + \Delta H^{(2)}$ Hamiltonian in Eq. (71) becomes easy-axis when $J < -2\Gamma$. Neglecting the effects of $\Delta H$ in Eq. (70), the critical value $J_{c2}(\Delta)$ is determined to be $J_{c2}(\Delta) \equiv -2\Gamma$. At $\Delta = 0$, this gives the point $(\theta_{c2} = 0.804\pi, \phi = 0.25\pi)$ in the phase diagram. Of course, the value of $J_{c2}(\Delta)$ must be shifted due to the effects of $\Delta H$ and higher-order effects of $\Delta H^{(2)}$.

5. Phase diagram around the FM2 point

Based on the above analytic analysis, we propose the following phase diagram which applies at least in a neighborhood of the FM2 point:

$$D_3$$-breaking I, II, \quad $\theta < \theta_{c1}(\phi)$;  
LL4, $\theta_{c1}(\phi) < \theta < \theta_{c2}(\phi)$;  
FM, \quad $\theta > \theta_{c2}(\phi)$,  

where we have expressed $J$ and $\Delta$ in terms of $\theta$ and $\phi$, and the ranges of $\theta$ all refer to the corresponding value of $\phi$. In the LL4 phase, the quantization axis for the longitudinal fluctuation is along the (111) direction in the six-sublattice rotated frame which becomes staggered in the original frame with possible site-dependent distortions as discussed in Sec. III C. However, the staggered sign in the definition of the coordinates in Eq. (69) indicates an FM-type quasi-long-range order in the six-sublattice rotated frame. Hence, no oscillation is drawn in the cartoon plot of the LL4 phase in Fig. 17.

C. Numerical results

1. The LL4 phase

The numerical studies on the Luttinger parameter reveal that the LL4 phase is rather narrow as shown in Fig. 2. While the phase transition line between the LL4 and FM phases can be clearly identified at the far end of the LL4 peninsula, it cannot be accurately determined close to the
equator since the Luttinger liquid behaviors in the LL1 phase percolate into the FM phase in finite size systems as discussed in Sec. III D. Thus the segment of the phase transition line between the LL4 and FM phases in the vicinity of the equator is plotted as a dashed rather than solid line in Fig. 2. Here we note an interesting observation. According to the discussion in Sec. VII A and Sec. VII B 4, a rough estimation of the range of the LL4 phase at $\phi = 0.25\pi$ is $0.51\pi < \theta < 0.80\pi$. However, as can be seen from Fig. 2, the actual range greatly shrinks compared with the above estimation. An explanation of why high-order terms have such a huge effect is worth further considerations.

### 2. The $D_3$-breaking I, II phases

Next we numerically study the spin ordering in the $D_3$-breaking I, II phases in Fig. 1. We emphasize that the six-sublattice rotated frame is taken, not the frame after the further two-sublattice transformation defined in Eq. (69).

As discussed in Sec. VC, a small field has to be applied to test the spin orders. We consider two types of fields: $h_I$ along $(-1, 0, 1)$ direction, and $h_{II}$ along $(1, -1, 1)$ direction. If the system is in the $D_3$-breaking I phase, then the field $h_I$ is able to polarize the system such that the spins are aligned according to the pattern in Eq. (97); on the other hand, if the system is

![Graph](image-url)

ED numerics are performed on $L = 18$ sites with periodic boundary conditions at $(\theta = 0.52\pi, \phi = 0.15\pi)$. Both $h_I$ and $h_{II}$ fields are taken to be $10^{-4}$.

in the $D_3$-breaking II phase, then an $h_I$ field will polarize the spins into the pattern in Eq. (102).

However, we note a difficulty of this method. In fact, the above method is not able to distinguish between the $D_3$-breaking I, II phases. Suppose the system is in the $D_3$-breaking I phase and subject to an $h_I$-field, then as can be seen from Fig. 19, the energies of two red circles located at $(0,−1,1)$ and $(1,−1,0)$ are lowered by the largest amount among the six solid red circles. Thus the system will end up with a linear combination of the two states represented by the red circles at $(0,−1,1)$ and $(1,−1,0)$. We will demonstrate that the spin expectation values in the state of such linear combination will exhibit the same pattern as the one in Eq. (102). Thus the $D_3$-breaking I phase will respond to the $h_I$ field in the same way as the $D_3$-breaking II phase.

To see the above point, recall that it is the unbroken symmetry group $\{TR_I\}$ of the state corresponding to the $(1,−1, I)$ vertex that determines the spin alignment pattern in Eq. (102). Denote $\Psi_{\theta}$ to be the state corresponding to the solid circle located at position $\vec{n}$ in Fig. 19. Then it is straightforward to verify that

$$TR_I\Psi_{(0,−1,1)} = \Psi_{(1,−1,0)}$$

$$TR_I\Psi_{(1,−1,0)} = \Psi_{(0,−1,1)}.$$  \hspace{1cm} (109)

Thus the linear combination

$$\Psi_{±} = \frac{1}{\sqrt{2}} \left[ \Psi_{(0,−1,1)} ± \Psi_{(1,−1,0)} \right]$$  \hspace{1cm} (110)

is invariant under $TR_I$ up to an overall sign. As a result, the spin expectation values in the state in Eq. (110) will exhibit exactly the same pattern as Eq. (102) (which applies to the $D_3$-breaking II phase) even though the system is within the $D_3$-breaking I phase. Despite such difficulty, we note that the applications of the $h_I$ and $h_{II}$ fields are still useful since they are able to test the existence of the $D_3$-breaking I, II orders, although not able to distinguish between the two.

Figure 21 shows the numerically measured expectation values of $S^\alpha_\vec{n}$ ($\alpha = x,y,z$) under $h_I$ and $h_{II}$ fields (both equal to $10^{-4}$) at a representative point $(\theta = 0.52\pi, \phi = 0.15\pi)$ within the $D_3$-breaking II phase in Fig. 1. ED numerics are performed on $L = 18$ system with periodic boundary conditions. As can be seen from Fig. 22, the patterns of $\langle S^\alpha_\vec{n} \rangle$ are consistent with Eq. (97) [Eq. (102)] under the $h_1$ ($h_{II}$) field shown as the black (red) data points. The magnitudes of both spin orders are huge (about $10^3$ times larger than the applied fields), indicating the existence of the two types of classical orders.

To determine in which phase the system resides, we further study the response of the system to a small field $h_0$ along the (111) direction. As can be inferred from Fig. 19, the $D_3$-breaking I phase does not respond to $h_0$, since the six solid red circles are perpendicular to the (111) direction. On the other hand, the $D_3$-breaking II phase should respond, as the field $h_0$ lowers the energies of the three states corresponding to the three solid blue circles located at $(1,1,−1), (0,1,1),$ and $(1,−1,1)$.

Figures 22(a) and 22(b) shows the energy change $\Delta E = E(h_0) − E(h_0 = 0)$ as a function of $h_0$ at several representative points in the negative $J$ region. Clearly, the system responds significantly at some of the points, whereas the response is nearly negligible at others. Based on the results in Figs. 22(a) and 22(b), we conclude that the points $(\theta = 0.52\pi, \phi = 0.2\pi, 0.24\pi)$ and $(\theta = 0.55\pi, \phi = 0.15\pi, 0.2\pi, 0.25\pi)$ are within the $D_3$-breaking I phase, whereas the points $(\theta = 0.52\pi, \phi = 0.15\pi, 0.3\pi)$ and $(\theta = 0.55\pi, \phi = 0.3\pi)$ are in the $D_3$-breaking II phase. Notice that the range of the $D_3$-breaking I phase expands by increasing $\theta$, which is consistent with the classical phase diagram as shown in Fig. 1.

As a further check, Figs. 22(c) and 22(d) displays the response of $\langle S^\alpha_\vec{n} \rangle$ to $h_0 = 5 \times 10^{-4}$ at several different points in the negative $J$ region. As is clear from Figs. 22(c) and 22(d), the point $(\theta = 0.52\pi, \phi = 0.24\pi)$ nearly has no response to the field, hence should locate within the $D_3$-breaking I phase. On the other hand, the response at the points $(\theta = 0.52\pi, \phi = 0.15\pi, 0.3\pi)$ are huge, and they should be within the $D_3$-breaking II phase.

FIG. 24. (a) $\langle S^x_\vec{n} S^y_{\vec{n}+\vec{L}} \rangle$, (b) $\langle S^y_\vec{n} S^y_{\vec{n}+\vec{L}} \rangle$, and (c) $\langle S^z_\vec{n} S^z_{\vec{n}+\vec{L}} \rangle$ vs $\sin(\pi \tau/L)$ at a representative point $(\theta = 0.74\pi, \phi = 0.5\pi)$ in the FM phase. DMRG numerics are performed on three system sizes $L = 48, 96,$ and $144$ with open boundary conditions.

VIII. THE FM PHASE

In Secs. III C, VI A, and VII B 4, we have inferred the FM phase based on RG analysis in three different regions, i.e., in
the region close to the emergent SU(2)$_1$ line on the equator of Fig. 1, the region close to the LL3 phase, and the region close to the LL4 phase. The spin alignments in the FM phase are shown to be

$$S_i = (a, a, b)^T. \tag{111}$$

A plot of the spin ordering in Eq. (111) is displayed in Fig. 23. Numerics have provided evidence for the FM order in Eq. (111). Figure 24 shows the correlation functions of spin-$1$ system sizes $L = 48, 96, 144$ with open boundary conditions. As can be checked from Fig. 24, the numerical results are consistent with Eq. (111). The extracted values of $a^2, b^2$ are $a^2 \approx 0.0484, b^2 \approx 0.0722$. We have checked several other points in the FM phase, and they all exhibit an FM order given by Eq. (111).

**IX. CONCLUSIONS**

In summary, we have studied the phase diagram of the spin-$1/2$ Kitaev-Heisenberg-Gamma chain. There are nine phases in total, including four Luttinger liquid phases, an FM phase, a Néel phase, a narrow d-Spiral phase in which the spins align in a distorted-spiral pattern, and $D_3$-breaking I, II phases. Good agreements are reached between analytic and numerical calculations for all the nine phases, though there is a narrow region close to the AFM Kitaev point on the equator where the nature of the phase diagram remains unclear and it is worth future investigations. Our comprehensive study of the phase diagram of the 1D generalized Kitaev model provides a road-map to the exotic physics in Kitaev materials.
